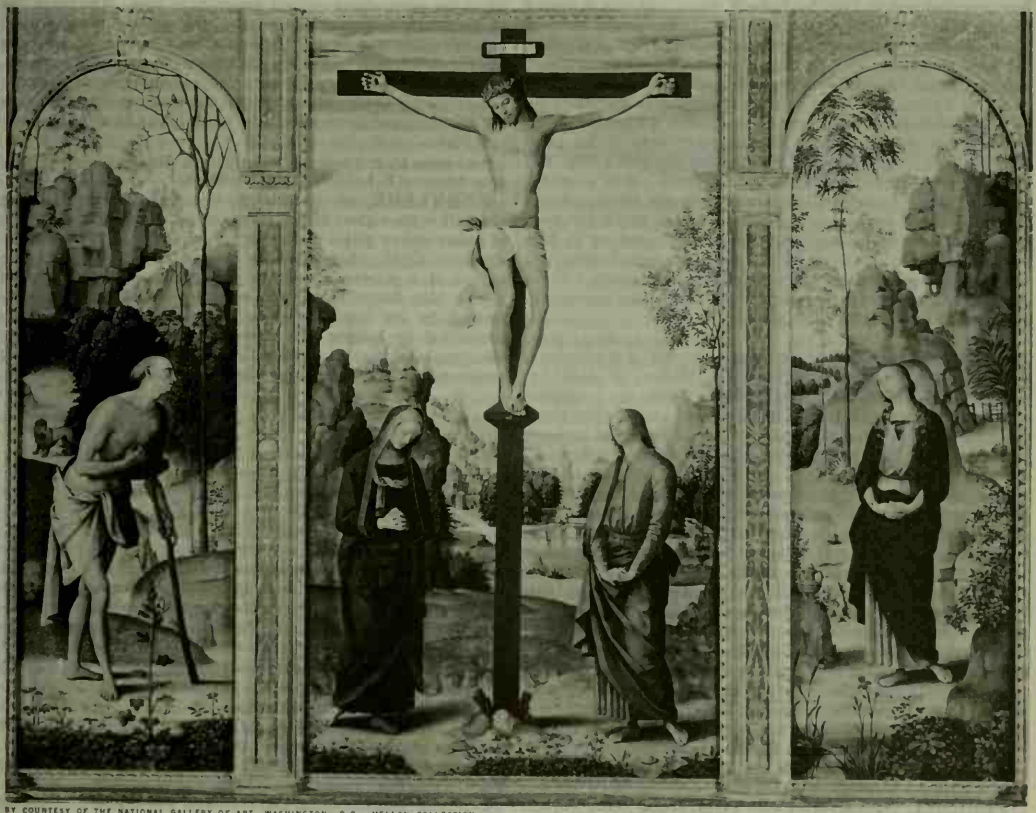
Between 1493 and 1496 he painted a fresco in the convent of Sta. Maria Maddalena de' Pazzi, in Florence. This takes up the entire wall surface, facing the entrance, of a room in the cloister. The roof is vaulted, so that the wall is divided into three bays by the corbels supporting the vaulting; below the corbels Perugino painted piers and made it seem that the room is in fact an open loggia, looking out on an extensive and beautiful Umbrian landscape, with the Crucifixion taking place in the central bay and the two side bays occupied by gently mourning saints. For the church of S. Pietro in Perugia he painted, between 1496 and 1498, a very large altarpiece of 15 panels. The central "Ascension" is now in the museum at Lyons, France, and other important parts are in the museum at Nantes, France, and in St. Gervais, Paris. A virtually identical "Ascension" is in Sansepolcro cathedral. In 1499 he was supposed to complete an altarpiece for the Certosa at Pavia, parts of which are now in the National gallery, London, and are an epitome of motives derived from Florentine art—the central Madonna owes a good deal to Fra Filippo Lippi, the archangel Michael derives from Donatello's statue of St. George, and the Raphael and Tobias is of a type used by the Verrocchio and Pollaiuolo workshops.

On Feb. 25, 1499, Perugino's name occurs for the first time in the records of the guild of bankers at Perugia; but, as the earlier books have been lost, the commission to paint a fresco cycle in



BY COURTESY OF THE NATIONAL GALLERY OF ART, WASHINGTON, D.C., MELLON COLLECTION

"THE CRUCIFIXION WITH THE VIRGIN, SAINT JOHN, SAINT JEROME AND SAINT MARY MAGDALEN," BY PIETRO PERUGINO. IN THE NATIONAL GALLERY OF ART, WASHINGTON, D.C.

their Sala del Cambio may well have been given earlier. He received the final payment in 1507; but it is generally assumed that the frescoes were completed shortly after 1500, the date which appears opposite Perugino's self-portrait on one of the pilasters. The ceiling is decorated with an Apollo surrounded by allegories of the planets. It has been shown that these scenes depend on the illustrations in Johannes de Spira's astrolabe tables, *Astrolabium planum in tabulis ascendens* (1494), and it is thought that the iconography of the whole Sala was planned by Francesco Maturanzio, a professor of rhetoric in Perugia. He certainly wrote the Latin verses which accompany the main fresco fields, representing allegorical figures of virtues and the principal exemplars of each virtue in classical antiquity or the Christian embodiment of it. The importance of these frescoes in the history of art lies in the fact that the young Raphael was Perugino's pupil around 1500 and probably had his grounding in fresco technique there. The figures of Fortitude and Horatius Cocles are often attributed to him. At about this date Perugino also painted an "Ascension" (Vatican), in which the sleeping soldier is sometimes attributed to Raphael; and the "Marriage of the Virgin" (Caen, France) is usually dated about 1503–04, since it seems to be the prototype of Raphael's finer "Sposalizio" (1504; Brera, Milan).

From this time Perugino's art began to decline, since he frequently repeated his earlier compositions in a routine manner. Vasari says that the critical Florentines began to lampoon him, and Perugino replied that they had once praised his work, and, if he now gave the same designs, they had no right to blame him. It is certainly true that the "Chastity" (now in the Louvre, Paris) was commissioned in 1503 by Isabella d'Este and was delivered only in June 1505, after a great many letters had passed between all concerned, at which time Isabella expressed herself as satisfied, but only moderately so. In fact, Perugino left Florence about 1505 and began to retire, working principally for the less critical public of Umbria. In 1508 he made a temporary comeback by painting roundels on the ceiling of the Stanza d'Eliodoro in the Vatican; but the commission for the room went to his pupil Raphael, who, in the few years after leaving Perugino's shop, had proved himself incomparably the greater artist. It is a curious fact that one of Perugino's last commissions was the completion in 1521 of some frescoes in S. Severo, Perugia, which had been begun years earlier by Raphael. He was still working in Feb. 1523, when he died of the plague at Fontignano, near Perugia, and was buried in a field there. The fresco of the "Nativity," in the National gallery, London, comes from Fontignano and is generally supposed to be Perugino's last work.

PERUTZ, MAX FERDINAND (1914–), British chemist, cowinner with J. C. Kendrew (*q.v.*) of the 1962 Nobel prize for chemistry for his studies on the structure of globular proteins, particularly hemoglobin, by X-ray diffraction analysis. He was born in Vienna on May 19, 1914, and studied at the University of Vienna. He began research on hemoglobin at Cambridge university in 1937 and received his doctorate there in 1940. After becoming a reader (lecturer) at the Davy-Faraday laboratory at the Royal institution, London, he was appointed director in 1947 of the Medical Research council's unit for molecular biology at Cambridge. He became a fellow of the Royal society in 1954.

Perutz developed special techniques, including the use of isomorphous derivates containing heavy elements, that made structural analysis of proteins feasible. Hemoglobin, which is responsible for the absorption and transport of oxygen in the blood, is a particularly difficult molecule to analyze structurally since it consists of four polypeptide chains (2α and 2β), each containing a heme group. One of the most important features of the crystallographic studies of Perutz and Kendrew is the elucidation of the conformation of the polypeptide chains in addition to the amino acid sequence. (D. T. EL.)

PERUZZI, BALDASSARE TOMMASO (1481–1536), architect and painter of the Italian Renaissance who first embraced high Renaissance ideals and developed into a Mannerist. He was probably born at Siena. He was a man of varied attainments, but his architecture, characterized by extreme simplicity and delicacy, was superior to his painting. A contemporary of Raphael and Donato Bramante, he first appeared in 1501 as a painter of frescoes in the chapel of S. Giovanni in Siena cathedral. His first architectural work was the Villa Farnesina (1509–11), for Agostino Chigi, which contains frescoes by Raphael and one—the "Story of Medusa"—by Peruzzi himself. In 1516 or 1517 he produced his best frescoes, those for the Cappella Ponzetti in Sta. Maria della Pace. On Raphael's death in 1520 Peruzzi was appointed architect for St. Peter's, jointly with Antonio Sangallo, the younger. About 1523 he built the classical portal of S. Michele in Bosco near Bologna. The Palazzo Ossoli (1525) and the Palazzetto Spada, both in Rome, have been attributed to him; also the Palazzo Albergati in Bologna. At the sack of Rome (May 1527) he escaped to Siena, became architect to the republic in July and architect to Siena cathedral in 1529. His most important building was the Palazzo Massimo alle Colonne (1535), in Rome. He died in Rome on Jan. 6, 1536, and was buried in the Pantheon.

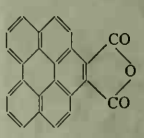
See W. W. Kent, *The Life and Works of Baldassare Peruzzi of Siena* (1925). (M. S. B.; X.)

PERVIGILIUM VENERIS, an anonymous Latin poem of 93 trochaic tetrameters catalectic, written for the eve of the festival of Venus. Date (between the 2nd and the 5th century A.D.) and authorship have occasioned much speculation: the argument from metre, which supports the otherwise ill-founded attribution to Florus (fl. 2nd century A.D.), equally points to the author (reputedly Tiberianus, fl. 335 A.D.) of the *Amnis ibat inter arva*, with which the poem shows marked similarity of tone. The poem has an irregularly recurrent refrain *cras amet qui numquam amavit quique amavit cras amet* ("Let love come tomorrow to him who has not loved, and to him who has loved let love still come tomorrow"); many have needlessly sought to impose regular strophic arrangement. Unobtrusive literary reminiscence is combined with the freshness and direct simplicity which later characterize medieval verse.

See edition by C. Clementi, 3rd ed. (1937) with bibliography; Eng. verse trans. by F. L. Lucas, *Aphrodite* (1948). (D. R. BR.)

PERYLENE, an aromatic hydrocarbon present in small amounts in the highest boiling fractions of coal tar. It crystallizes in golden-yellow plates and has a melting point of 273°–274° C. Perylene, $C_{20}H_{12}$, has also been isolated from a sulfur dioxide extract of a petroleum distillate. Its dilute solutions have an intense blue fluorescence. The structure (I) of perylene is indicated by its formation from naphthalene and from 1:1′-dinaphthyl by heating with aluminum chloride and from 1:8-diiodonaphthalene by heating with copper. This is confirmed by synthesis from 9:10-bischloromethylanthracene.

I



II

Perylene has, to a certain degree, the character of a diene and reacts with maleic anhydride in boiling nitrobenzene (*i.e.*, under oxidizing conditions) to give 1:12-benzoperylene-dicarboxylic anhydride (II), which may be decarboxylated to 1:12-benzoperylene, also a minor constituent of coal tar. Oxidation of perylene with chromic acid gives the 3:10-quinone, derivatives of which occur naturally as pigments in aphids. (J. W. CK.)

PESAH: *see* JEWISH HOLIDAYS.

PESARO (Roman PISAURUM), a town and seaport of the Marches, central Italy, capital of the province of Pesaro e Urbino, is situated on the Adriatic coast and on the right bank of the Foglia (Pisaurus) river 60 km. (37 mi.) N.W. of Ancona by road. Pop. (1961) 66,985 (commune). It is on low ground surrounded by hills and is the centre of a rich agricultural district. Pesaro is also a pleasant sea bathing resort on the main coastal railway and

road. On the western slope of the Monte di San Bartolo lies the Villa Imperiale which was built by Alessandro Sforza; its foundation stone was laid by the emperor Frederick III during his journey to Italy in 1469 and the building is noted for fine stucco ceilings, wall paintings and pavements of majolica plaques. A new palace was begun in 1530 by Girolamo Genga and his son, Bartolomeo, for Eleonora Gonzaga but it was never completed. The old walls were in 1830 transformed into a public promenade. Other buildings include a palace built in 1455–65 for the Sforza, and restored by Francesco Maria I della Rovere, duke of Urbino, in the 16th century, where antiquities, pictures and a fine collection of majolica (the best in Italy) from the old Urbino and other manufactories were preserved (they are now in the civic museums); and the fortress of Rocca Costanza (begun by Costanzo Sforza in 1474, Luciano Laurana being the architect). The cathedral has a 14th-century façade. The composer Gioachino Antonio Rossini, who was born at Pesaro, left his fortune to found a music school, the Liceo Musicale Rossini, famous for its directors and for the composers who studied there. The civic museums contain part of the collection of the Mosca museum. They also house the picture gallery and the ceramics which were once in the Palazzo Ducale (1450–1510), which survives. The Oliveriano Archaeological museum is important in the study of Italian antiquities.

Destroyed by Vitiges the Goth, the town was restored and strengthened by Belisarius, and afterward along with Ancona, Fano, Senigallia and Rimini formed the Pentapolis Maritima ("five maritime cities"). In the course of the 13th century Pesaro was sometimes under the government of the popes, sometimes under that of the emperors, but the Malatesta family, which first took root in the city about 1285, gradually became the real masters of the place. In 1445 they sold their rights to Francesco Sforza; and in 1512, through the influence of Pope Julius II, the Sforza were supplanted by his nephew Francesco Maria I della Rovere and Pesaro became the residence of the dukes of Urbino until the death of Francesco Maria II della Rovere in 1631, when it reverted to the Papal States. Pesaro, a main point at the Adriatic end of the so-called "Gothic line," suffered in World War II during the Allied advance of 1944, but fortunately many old buildings escaped with minor damage. (X.; I. Z.)

PESARO E URBINO PROVINCE (area 1,117 sq.mi. [2,893 sq.km.]; pop. [1961] 301,226) is the most northerly province of the Marches. It is mainly occupied by the Apennines and their spurs which run to the coast, intersected by valleys and drained by the parallel rivers Metauro, Foglia and Marecchia. The republic of San Marino borders it on the north. It is largely agricultural and pastoral. There was formerly a tradition of leatherworking; silk and ceramic industries are still carried on; and motorcycles, furniture and stockings are manufactured. Chief towns, besides Pesaro and Urbino (*q.v.*) are Fano (*q.v.*), Cagli, Fossombrone, Pergola and Urbania. (X.)

PESCADORES (P'ENG-HU LIEH-TAO), a group of 64 islands of volcanic and coral origin in Formosa strait separated from Taiwan (Formosa) by the 30-mi. (48-km.) wide P'eng-hu or Pescadores channel. Land area 49 sq.mi. (127 sq.km.); gross area more than 1,000 sq.mi. (2,590 sq.km.). The largest islands are P'eng-hu, Pai-sha (connected with P'eng-hu by causeway), Yü-weng and Pa-chao. Relief is low, less than 300 ft. (91 m.) above sea level, and coral reefs are common. The islands are washed by the warm Kuro Shiwo (Japan) current and the climate is frost free. Mean monthly temperatures range between 15° C. (59.5° F.), in February and 28° C. (82° F.), in July. Except for summer, prevailing winds are northerly and frequently of gale force. Almost all of the 38-in. average annual rainfall falls between June and September. Soils derived from basalt are sandy; those from coral reefs, droughty; natural vegetation is sparse.

Rich fishing grounds nearby explain the Portuguese-derived name Pescadores (fishermen's islands).

The population (1956) was 85,886, consisting primarily of Chinese from neighbouring Fukien province. More than half of the inhabitants reside on P'eng-hu island (site of P'eng-hu, the principal town).

MAJOR ISLANDS OF THE PESCADORES

Fishing and farming are the major occupations. Although 59% of the land is arable, poor soils and high winds make cultivation difficult. Millets, fruits (some exported), corn, sweet potatoes and peanuts are the chief crops.

The Pescadores were occupied by the Dutch (1622–24), by the French and ceded to Japan (1895–1945). The islands, long a dependency of Formosa (*q.v.*), became one of the 16 *hsien* of Taiwan province in 1950. (N. S. G.)

PESCARA, FERNANDO FRANCISCO DE AVALOS, MARCHESE DI (1490–1525), Spanish-Neapolitan *condottiere*, pre-eminent in the service of Spain and of the Holy Roman Empire, was born in Naples, the son of Alfonso de Avalos, 1st marchese di Pescara. At the age of six he was betrothed to Vittoria Colonna (*q.v.*), and the marriage was celebrated in 1509.

Pescara's military career began in 1512, when he fought on the Spanish side at the Battle of Ravenna and was wounded and captured by the French. He was released on payment of a ransom and a promise never again to fight against the French; but the engagement was not observed, and during the following years he rendered conspicuous service to the Spanish and imperial cause in successive Italian campaigns. He defeated the Venetians at Vicenza in 1513, took Padua in 1514, and conquered Milan in 1521 and Genoa in 1522. On the death in 1523 of Prospero Colonna, who had trained him in arms, Pescara became lieutenant general and effective commander of the imperial troops in Italy. Fresh victories followed, at Romagnano in Piedmont in 1524 and at Pavia (*q.v.*) in 1525.

It is with this Battle of Pavia, his military masterpiece, that Pescara's name is indelibly associated. The odds seemed against him. His troops were ill-paid, ill-fed, and in danger of defection to the enemy. Yet by tenacity, patience, and tact, Pescara overcame all obstacles: on Feb. 24, 1525, he defeated the French by a brilliant attack and captured their king, Francis I.

Pescara died at Milan on Dec. 2, 1525. The final months of his life were obscurely involved with the so-called conspiracy of

Girolamo Morone, lieutenant of the nominal duke of Milan, Francesco Sforza, the purpose of which was to unite Italy in alliance with France against the emperor Charles V and the Spaniards. Pescara was offered the crown of Naples and may for a time have wavered in his loyalty. In the end he betrayed the plot and had Morone arrested (Oct. 15, 1525); but on his deathbed he recommended mercy and his plea was heard.

BIBLIOGRAPHY.—P. Giovio, *La Vita di Ferrando Davalo, marchese di Pescara* (1551); K. Brandi, "Nach Pavia," *Nachrichten von der Gesellschaft der Wissenschaften zu Göttingen* (1939); P. Pieri, *Il Rinascimento e la crisi militare italiana* (1952). (P. J. J.)

PESCARA, chief town of Pescara province, region of Abruzzi e Molise, central Italy, lies on the Adriatic coast at the mouth of the Pescara river 93 mi. (150 km.) S.S.E. of Ancona by road. Pop. (1961) 86,834 (commune). The town has two centres, Pescara Riviera on the right bank, and Castellamare Adriatico on the left. Notable buildings include the Tempio della Conciliazione, the house where Gabriele d'Annunzio, the poet, was born in 1863, the large post office and the governor's palace. Pescara is a seaside resort and a tourist centre and has summer festivals. It is on the railway and main road from Bologna to Bari and Brindisi. Fishing, the manufacture of machinery and textiles, and food processing are carried on. There are naval shipyards.

The Roman Aternum, the town was almost destroyed in the barbarian invasions and arose again in the early middle ages as Piscaria (*i.e.*, "abounding with fish"). It has been the scene of much fighting throughout its history and suffered damage in World War II.

PESCARA PROVINCE has a population (1961) of 229,841 and an area of 473 sq.mi. (1,225 sq.km.). Principal products are grapes, olives and vegetables. Bussi Sul Tivino has chemical, asphalt and bitumen industries; Cavamanico has medicinal waters; Popoli is known for its 15th-century Taverna Ducale; and Casauria for the Cistercian abbey of St. Clement (11th–12th centuries).

(M. T. A. N.)

PESCENNIUS NIGER: *see* NIGER, PESCENNIUS.

PESELLINO (FRANCESCO DI STEFANO [GIUOCHI]) (1422–1457), Florentine painter of the early Renaissance. He was brought up by his grandfather, the painter Giuliano il Pesello (1367–1446), and worked as his assistant until Giuliano's death, when he became associated with Fra Filippo Lippi. In 1453 he went into partnership with Piero di Lorenzo di Pratese and during this period began, for the church of S. Trinità at Pistoia, the altarpiece of the Trinity that later was moved to the National gallery, London. It was left unfinished at his death on July 29, 1457.

Pesellino excelled in the execution of paintings on a small scale and is famous for his *cassone* pictures, intended for the decoration of marriage chests, in which he illustrated, in charming tapestry-like designs, an old legend or tale; several of these are in the Gardner museum, in Boston. A number of works by Pesellino may be seen in galleries in the United States; among these are the National Gallery of Art, Washington, D.C.; the Metropolitan Museum of Art, New York city (a fine panel of the Madonna and saints); and the Museum of Art of Toledo, O.

PESHAWAR, a municipal town, district and division located in West Pakistan. The town, headquarters of the district and division, stands about 1,048 ft. above sea level near the left bank of the Bara river, 11 mi. from Jamrud and the entrance to the Khyber pass, 190 mi. E.S.E. of Kabul, Afg., and 276 mi. N.W. of Lahore. Pop. (1961) 218,691 including the cantonment. Formerly it was enclosed with a protective wall with 16 gates, but this was partially removed to allow for expansion. The cantonment, 2 mi. W., is the largest military headquarters on Pakistan's western frontier, and of great strategic importance because of its proximity to the Khyber pass (*q.v.*). For many centuries the *powindahs*, or Afghan traveling merchants, led their caravans every autumn to Peshawar from Kabul, Bukhara and Samarkand. The ancient Qissa (Kissa) Kahani bazaar (the street of storytellers) is the meeting place of merchants from many lands who deal in dried fruits, wool, woolen products, rugs, carpets, *postins* (sheepskin coats), karakullis (lambskin caps) and Chitrali *choghas* (cloaks). The historic buildings include: Balahissar, a fort built by the Sikhs on the ruins of the state residence of the Durranis, which was destroyed by them after the battle of Nowshera; Gor Khatri, once a Buddhist monastery and later a sacred Hindu temple, which stands on an eminence in the east and affords a panoramic view of the entire city; the pure white mosque of Mahabat Khan (1630), a remarkable monument of Mogul architecture; Victoria memorial hall; the museum (1906) with Gandharan sculptures and other antiquities; and government house. The government offices and modern hotels, the Peshawar club and the Sadar bazaar are in the cantonment area. There are many parks while the Chowk Yadgar and the town hall are other places of social and public assembly. *Qahwah-Khanas*, or coffee houses, are popular. There are a number of colleges affiliated to Peshawar university (established 1950) and several schools. The chief cottage industries are the manufacture of copper utensils and leather goods, especially the *chappals* (slippers) and shoes (plain and embroidered), wax and needlework, glazed earthenware, knives and small arms. The town commands the trade with Afghanistan and central Asia.

Peshawar is one of the oldest historic cities of Pakistan. Once the capital of the ancient kingdom of Gandhara (*q.v.*), it was known variously as Parashawara and as Purushapura (the seat of Purush or Porus; *q.v.*). It was also called Begram, which frequently occurs in the history of the Moguls and in classical Pashto (Pushtu) poetry. The present name Peshawar (Pesh Awar or "frontier town") is ascribed to Akbar.

History.—References to the Peshawar area occur in early Sanskrit literature and in the writings of Strabo, Arrian and Ptolemy. It once formed part of the Buddhist kingdom of Gandhara, and the area is still studded with crumbling stupas. Rock edicts of Asoka are found at Shahbazgarhi and Mansera (Mansehra). The Peshawar valley was annexed by the Greco-Bactrian king Eucratides in the 2nd century B.C. About the beginning of the Christian era it came under the Kushans, whose most powerful ruler Kanishka made Purushapura his capital. The Kushans were turned out by Hephthalites (White Huns). In the 10th century the Ghaznevid Subuktigin defeated Raja Jaipal there. Between the 15th and 16th centuries the district was occupied by Pathan tribes from what is now Afghanistan and the Mogul emperors always found difficulty in maintaining their authority over them. Peshawar was a favourite residence of the Afghan dynasty founded by Ahmad Shah Durrani, and there Mountstuart Elphinstone went as British ambassador to Shah Shuja in 1808. A few years later Ranjit Singh crossed the Indus, and Sikh authority was firmly established under Gen. Paolo di Bartolomeo Avitabile in 1834. In 1849 Peshawar passed to the British. In 1901, it became part of the Northwest Frontier province, and in 1955 of West Pakistan.

PESHAWAR DIVISION, as reorganized on Dec. 9, 1960, includes the districts of Mardan, Hazara, Peshawar and Kohat, with their special attached areas, and the Malakand, Mohmand, Khyber and Kurram agencies. Area 28,153 sq.mi. Pop. (1961) 6,372,467. Most of the Peshawar and Mardan districts constitutes a great basin, drained by the Kabul river eastward, north of the Khyber pass, until it falls into the Indus above Attock. Much of the Peshawar valley is covered with surface gravels and alluvium. In the northeast lies the mountainous Hazara district, drained by the Kunhar which constitutes the famous Kaghan valley, a growing tourist area. Similarly the Malakand and Mohmand agencies north of the Kabul river, and the Khyber and Kurram agencies and Kohat district, to the south, are intersected by many hills separated by small valleys. The Malakand pass leads into Swat state in the north, and the Kurram pass to Kabul in the west. Wheat, barley, maize (corn) and bajra are the chief food crops and sugar cane and tobacco the principal cash crops. There are power stations at Malakand and Dargai, each with an installed capacity of 20,000 kw. and at Warsak with a planned capacity of 240,000 kw.

PESHAWAR DISTRICT (area 1,646 sq.mi.; pop. [1961] 1,213,468) consists mainly of highly irrigated plains, apart from the area covered by low hills at Cherat in the southeast. Wheat, maize (corn) and sugar cane are the chief crops. The inhabitants are mostly Pathans with some Hindkis, Awans forming the most nu-

merous Hindki tribe. Nowshera, 25 mi. E. of Peshawar, is an important cantonment with industrial development. (K. S. Ad.)

PESHITTA, an ancient version of the Bible in Syriac. The word means "simple," referring to the fact that the version is without the elaborate critical apparatus of other Syriac versions. The translation of the Old Testament was accomplished over a long period of time, probably beginning in the 2nd or 3rd century. The New Testament probably dates from the late 4th century. Following the canon of the Syrian Church, the Peshitta does not have II Peter, II and III John, or Jude. The version was adopted by both the Jacobites (*i.e.*, Syrian Christians adhering to the Syrian Orthodox Patriarchate of Antioch; *q.v.*) and Nestorians (*q.v.*). The oldest firmly dated copy of any Bible manuscript in any language is a Peshitta manuscript of the Pentateuch of A.D. 442. *See* also Syriac Literature.

PESNE, ANTOINE (1683–1757), French painter of historical subjects and portraits and court painter in Berlin, was born on May 23, 1683, in Paris. After being taught by his father, Thomas Pesne, and his maternal great-uncle, Charles de LaFosse, Pesne later studied at the Paris academy, where he was influenced by the leading French portraitists, Hyacinthe Rigaud and Nicolas de Largillière. In Rome and Naples, and particularly in Venice, where he studied with Andrea Celesti, Pesne developed a marked colouristic talent. The elegant style of his early portraits was greatly influenced by the paintings of his countryman Jean Raoux, as well as by Dutch masters and the elegant pastels of the Venetian artist Rosalba Carriera.

In 1707 Pesne's full-length portrait of the Prussian ambassador to Venice, von Kyphausen, attracted the attention of Frederick I of Prussia; and the artist was appointed court painter to the royal court of Berlin, where he remained, except for short intervals, from 1710 until his death on Aug. 5, 1757. Pesne became the portraitist of the court and of the aristocracy and eminent personages of Brandenburg-Prussia. When Frederick II came of age, Pesne was able to give full scope to his colouristic gifts in mythological and allegorical ceiling paintings and murals, decorating the interiors of the palaces at Rheinsberg, Charlottenburg, Berlin and Potsdam. He continued to paint portraits, some of which achieve by their brushwork and brilliant colouring an almost impressionistic effect reminiscent of Renoir. Of special interest are the various representations of Italian and French dancers and actresses whom Frederick II engaged for the Berlin Opera. They are in the style of Watteau, but as the first European painter to give these portraits an individual character, Pesne developed here the most famous side of his work.

Bibliography.—C. F. Förster, article on Pesne in Thieme-Becker, *Allgemeinen Lexikon der Bildenden Künstler,* vol. xxvi, p. 467 ff. (1932); E. Berckenhagen *et al., Antoine Pesne,* with introduction by G. Poensgen (1958); catalogue of the Pesne bicentenary memorial exhibition in Berlin (Nov. 1957). (G. Pn.)

PESO, a monetary unit first introduced into Spain by Ferdinand and Isabella, who reformed the Spanish coinage system in 1497; it did not come into common use until the time of Charles I (1516–56; the emperor Charles V). The modern peso, equal to 100 centavos, is the monetary unit of several Latin-American countries and of the Republic of the Philippines. Originally divided into eight reales, the peso became the basis of the silver coinage of the Spanish empire after the monetary reform of 1772–86. In the Americas it was called "piece of eight" or "Spanish milled dollar," and was, in fact, equivalent to the U.S. silver dollar. It was retained as the basic coin by most of the Spanish colonies in America when they gained their independence. When these countries adopted the decimal system for their coinage, a local name was in several cases substituted for the term peso. Thus, it was renamed sol in Peru in 1863, bolivar in Venezuela, sucre in Ecuador, colón in El Salvador and Costa Rica, balboa in Panama, lempira in Honduras, quetzal in Guatemala, córdoba in Nicaragua, and boliviano in Bolivia. Other countries, such as Argentina, Chile, Colombia, Cuba, Mexico, and Uruguay, continued to use the term and the denomination peso. Even where the name was officially changed, peso continued to be used in popular speech. (Jo. M. L.)

PESSANHA, CAMILO (1867–1926), the representative in Portuguese poetry of symbolism at its purest and most genuine and the chief precursor of so-called "modernist" poetry. He was born in Coimbra, Sept. 7, 1867, the son of an undergraduate and a girl of the lower classes. He went to the grammar school in Coimbra and entered the faculty of law at the university there, concluding his studies in 1891. After being employed as an assistant to the public prosecutor in Mirandela, he was appointed head of the philosophy department at the Liceu at Macao. He went to this colony in China in 1893 and remained there, apart from two or three visits home, until his death in 1926. From the beginning Pessanha assumed oriental customs, including the opium habit, attracted to them by his somewhat passive temperament. He learned Cantonese and was one of the last Portuguese men of letters to speak the Chinese language, from which *inter alia* he translated some elegies, *Oito Elegias Chinesas,* accompanied by a preface that demonstrates his knowledge of oriental literature. He also collected Chinese *objets d'art* which he bequeathed to the Museu Machado de Castro in Coimbra. His writings on China, in particular the *Introdução a um Estudo sobre a Civilização Chinesa* and the *Elegias,* were collected in *China* (1943). Although he began to write verse in Coimbra, Pessanha was virtually unknown until 1916 when his poetry, which unites the purest symbolist spirit with the most modern poetic technique, was made known to a new generation in the pages of a progressive review, *Centauro.* Collected in the volume *Clepsidra* (1920), his poetry became a kind of breviary for the modernist poets. Musical, subtle, penetrated by the mystery of oriental poetry, Camilo Pessanha is one of the most lyrical of Portuguese poets.

See A. Dias Miguel, *Camilo Pessanha* (1956); Ester de Lemos, *A "Clepsidra" de Camilo Pessanha* (1956); J. Gaspar Simões, *Historia da Poesia Portuguesa do seculo XX* (1959). (J. G. Ss.)

PESSIMISM, a word coined in modern times (from Latin *pessimus,* worst) to denote an attitude of hopelessness toward life and toward existence, coupled with a vague general opinion that pain and evil predominate in the world; the antithesis of "optimism," which denotes an attitude of general hopefulness, coupled with the view that there is a balance of good and pleasure in the world. To describe an attitude as pessimistic need not, however, mean that it involves no hope at all: it may locate its objects of hope and of appraisal in a region beyond ordinary experience and existence; and it may also direct such hope and appraisal to the complete cessation and cancelling of existence.

Unsystematic pessimism is a reflection of material circumstances, of bodily health or of general temperament; it is characteristically expressed in the language of *Ecclesiastes* that "all is vanity." There are, however, systematic forms of pessimism, both philosophical and religious. The Orphic-Pythagorean view of the world was one of qualified pessimism, fleshly existence being regarded as a periodic penance undergone by the impure or guilty soul, until it can at last be freed from the "cycle of becoming" by ceremonial purification or by philosophical contemplation. This same qualified pessimism in regard to fleshly existence and experience is found in Platonism, for which things in this world necessarily deviate from and fall short of their ideal exemplars and for which (as in the *Phaedo*) fleshly tendencies and experiences only represent hindrances in the carrying-out of activities which will be fully performed after death. Eastern pessimism (of a qualified sort) may be illustrated in Buddhism, where all conscious personal existence is held to involve pain or ill, where the cause of such ill lies in personal striving or desire and where positive appraisal is directed to a consummation (*nirvana*) which involves the cessation of striving and of conscious personal existence. It is similarly represented in the main currents of Hindu thought, with the additional thesis that the world is not only painful and evil but also illusory. A qualified pessimism is, of course, deeply characteristic of Christianity, where our world is a fallen world, in which human reason and will are corrupted, and where it is only by redemptive action coming from beyond the world and fulfilling itself in another order that such ills can be rectified.

Philosophical pessimism was strong in the 19th century and was represented in the systems of Arthur Schopenhauer and Karl Robert Eduard von Hartmann. Schopenhauer presented a synthesis of Kantianism and Buddhism, the Kantian thing-in-

itself being identified with a blind irrational will behind phenomena; our world, being the manifestation of such an unhappy will, must itself be unhappy. In the first half of the 20th century critical philosophy tended to steer clear of the whole issue of optimism *versus* pessimism; feeling themselves incompetent to make many general assertions about the world, philosophers were particularly unwilling to make general assessments of its goodness or badness. A qualified pessimism in regard to the world and to human nature was, however, characteristic of several theological systems (*e.g.*, the theologies of Karl Barth, of Emil Brunner and of the Dutch neo-Calvinists Herman Dooyeweerd and D. H. T. Vollenhoven). Perhaps the most uncompromisingly pessimistic system ever developed is that of the existentialist philosopher Martin Heidegger for whom death, nothingness and anxiety are central topics of interest and for whom the highest possible act of human freedom is a coming to terms with death.

PESSINUS (PESSINOUS, PESINOUS), the most famous of the ancient holy cities of Asia Minor, situated in Galatia, below Mt. Dindymus, by the Sangarius (Sakarya) River. The ruins, discovered by C. Texier in 1834, lie around the village of Ballihisar,, 9 mi. (14½ km.) SSE of Sivrihisar in the modern Turkish *il* (province) of Eskisehir. Originally a Phrygian city, it became the capital of the Galatian tribe Tolistoagii (or Tolistobogii) and the chief commercial city of the district.

From Pessinus the image and the cult of the Anatolian Great Mother of the Gods (*q.v.*; or Cybele) were introduced to Rome in 204 B.C. The goddess, here called Agdistis, had a wealthy and celebrated temple. Her priests were also princes, who ruled not only in the city (the coinage of which, beginning about 100 B.C., was for long issued by them) but also in the surrounding country, deriving a large revenue from the temple estates; but in the time of Strabo (A.D. 19–20) their privileges were much diminished. Some time before 164 B.C. Pessinus was taken over by the Gauls, and the membership of the priestly college was then equally divided between the Gauls and the old priestly families. Like Ancyra and Tavium, the other Galatian centres, Pessinus was romanized first and hellenized afterward. With Roman encouragement it developed during the first two centuries A.D. from a tribal capital to a city of the normal Greek type. Christianity cannot be traced before the 4th century. When Galatia was divided into two provinces (3rd or 4th century A.D.), Pessinus was made the capital of Galatia Secunda or Salutaris, and it became a metropolitan bishopric. By the 9th century it seems to have been replaced by Justinianopolis, and was probably deserted by then. The ruins were largely dismantled and used for building at Sivrihisar.

PESSOA, FERNANDO ANTÓNIO NOGUEIRA (1888–1935), the greatest literary figure in Portuguese "modernism," the movement which gave Portuguese literature of the first half of the 20th century its European significance. He was born in Lisbon on June 13, 1888. His father died when Pessoa was five and his mother married the Portuguese consul in Durban, and in 1895 took him to South Africa where he was educated. In 1903 he was outstandingly successful in the entrance examination of Cape Town university, winning the Queen Victoria prize for English style. In 1905 he returned to Portugal, and enrolled at the Curso Superior de Letras in Lisbon in 1906 but ceased to follow the courses there in the following year and sought openings in commercial life, in which he displayed much initiative but a total absence of tact. He eventually settled down as foreign correspondent for various commercial firms in Lisbon. Though he tried at different times to fend for himself, he always returned to lodgings, first with an aunt and later with his half sister. A bachelor and not particularly sociable, he preferred the acquaintanceship of fellow solitaries in the cafés to the solid joys of a settled family life. A doleful existence, though sublimated by his intelligence and tempered by nostalgic evocations of his childhood, lies behind his work, most of which was unpublished at the time of his death in Lisbon, Nov. 30, 1935.

In the previous year Pessoa had published his first book in Portuguese, *Mensagem*. All that was known of his work at his death were some booklets of poems in English—a language which Pessoa, who was virtually bilingual, wrote with ease—*Antinous* and *35 Sonnets* (1918) and *Inscriptions* (1920), collected in three volumes under the title *English Poems* (1921); some literary and political manifestoes—*Aviso por Causa da Moral* (1923) and *Interregno* (1928); his editorship of the review *Athena* (1924–25) and his frequent contributions to the avant-garde reviews, especially *Orpheu* (1915), the organ of the modernist movement in which Pessoa, with Mário de Sá-Carneiro and José de Almada Negreiros, was a leading spirit. The posthumous edition of his complete works consists of eight volumes; the poems are grouped under the various names or pseudonyms which the poet employed during his lifetime, each name purporting to represent one of the different personalities which he felt to exist within himself: the personality and the style can vary, therefore, according to whether a poem is signed by Fernando Pessoa himself, "Alberto Caeiro," "Álvaro de Campos" or "Ricardo Reis." The most important volumes in the collected edition are *Poesias de Fernando Pessoa* (1942), *Poesias de Álvaro de Campos* (1944), *Poemas de Alberto Caeiro* (1946) and *Odes de Ricardo Reis* (1946), in addition to the *Mensagem* of 1934. Examples of his prose writings as a critic and thinker of a paradoxical spirit can be found in the collection entitled *Páginas de Doutrina Estética* (1946). A good selection of his work, with an introduction, is in A. Casais Monteiro, *Fernando Pessoa* (1945).

See J. do Prado Coelho, *Diversidade e Unidade em Fernando Pessoa* (1949); J. Gaspar Simões, *Vida e Obra de Fernando Pessoa*, 2 vol. (1950).
(J. G. Ss.)

PESTALOZZI, JOHANN HEINRICH (1746–1827), Swiss educator, revered in Switzerland because of his tireless efforts to aid poor, orphaned and helpless children, was born at Zürich on Jan. 12, 1746. Active even in his student days in Zürich in social and political reform, he early earned a reputation as champion of the underprivileged and exploited. He established (1774) an orphanage, where he attempted to teach neglected children the rudiments of agriculture and simple trades that they might lead productive, self-reliant lives. This philanthropic experiment failed in 1780, and Pestalozzi, in a period of despair, wrote what can be considered a key to his philosophy, *The Evening Hour of a Hermit*, a profound and moving series of reflections and aphorisms.

During the next decade he published a widely read four-volume novel, *Leonard and Gertrude*, which delineated and publicized his ideas on social, moral and political reform. When the town of Stans was destroyed and the inhabitants massacred during the Napoleonic invasion of 1798, Pestalozzi collected several dozen destitute children and cared for them under most arduous and pitiful conditions.

In 1805 Pestalozzi founded at Yverdon his famous boarding school, which flourished for 20 years, was attended by students from every country in Europe and was visited by hundreds of the most important figures of the time. Pestalozzi's overarching educational principle, elaborated in *How Gertrude Teaches Her Children* (1801), was "sense impression": accurate, clear thinking is dependent upon accurate observation of actual objects; words and ideas thus have meaning only when related to concrete things. The Yverdon curriculum, therefore, emphasized such pupil activities as drawing and writing, singing, physical exercise, group rather than individual recitations, models, collections, map making and field trips. Carefully graded instruction, allowance for individual differences, and ability groupings were novel features. An important undertaking was the teacher-training department.

Educators journeyed to Yverdon to study "the method," carried Pestalozzi's ideas throughout Europe and America and established scores of Pestalozzian schools. Froebel and Herbart learned much from Pestalozzi, as did Ritter, the geographer. The object-lesson approach used in a highly successful Pestalozzian school in England, conducted by Charles and Elizabeth Mayo, was adopted in the United States (1861) by the Oswego, N.Y., normal school

and became the guiding principle in some of the country's foremost teacher-training institutions.

Pestalozzi's greatest influence was upon Prussia. The German philosopher Fichte, indeed, told a Germany prostrated at Jena that only through a strong educational system based upon Pestalozzian principles could the country expect to recover. Pestalozzi died at Brugg on Feb. 17, 1827.

There are several German editions of Pestalozzi's collected works. His writings referred to above, and *Letters on Early Education*, have been translated into English.

BIBLIOGRAPHY.—L. F. Anderson (ed.), *Pestalozzi* (1931); J. A. Green and F. A. Collie (eds.), *Pestalozzi's Educational Writings* (1912). Of numerous biographies and commentaries, *see* Roger de Guimps, *Pestalozzi: His Life and Work*, Eng. trans. by John Russell (1880); and J. A. Green, *Life and Work of Pestalozzi* (1913). M. R. Walch's *Pestalozzi and the Pestalozzian Theory of Education* (1952) contains an excellent bibliography. (J. C. Od.)

PEST CONTROL. Man survives by constant vigilance against encroaching natural forces that he deems inimical to his own highly organized society. Although his mastery does not yet extend to the overwhelming physical phenomena on all sides, it does include an influence over the organisms that not only compete with man for food or space but also damage his possessions or attack him personally. Man therefore endures in his present state only so long as he can effectively control these competitors or pests.

Criticisms have been voiced by many biologists that man, with his limited knowledge of biotic interrelation and his myopic view of the outcome of his actions, is doing irreparable harm in many ill-advised programs of pest extermination, both to the numerous organisms beneficial, or at least innocuous, to man and to the human species itself. These cogent alarms have inspired widespread discussion and a needed reappraisal of policies and practices of pest control.

The concept of "pest" is interpreted very subjectively, of course. An ecologist would not necessarily consider several leaf-eating caterpillars on a plant as pests, whereas the gardener who cultivated the plant might very well draw up a plan of action against the intruders. And only one bat, rat or mouse is enough to qualify as a household pest. However, to truly merit the designation of pest as the term will be used in this article, an animal or plant must occur in such abundance as to present a distinct threat to man or to his interests, economically or medically.

This article examines the biological background to pest build-up, discusses the various ways, both artificial and natural that can be used to combat the competitors and draws attention to their merits and demerits. In particular, it emphasizes the need for care in the use of "blunderbuss" methods such as the exclusive or unnecessary use of chemicals; it is hoped that ways and means can be found for man to achieve his aim of increasing production with a minimum of disturbance to the soil and the fauna and flora dependent upon it.

HOW PESTS ARISE

Nature: Stability in Diversity.—In the wild, many kinds of plants intermingle to produce a complex mosaic that varies both horizontally and vertically. These plants provide the food for a number of different animals, many of which in turn become the food for a second group of feeders. This process of eating and being eaten continues upward through the various consumer levels so that the energy stored in any particular plant may be transferred through as many as four or five different types of animals to establish what is generally called a food chain. In view of the great variety of food sources it is not surprising to learn that less than two square miles of English countryside, Wytham Woods, contains at least 2,500 different species of animals. In these vast assemblages each group of the smaller plant-eating (phytophagous) animals is restricted somewhat to suitable food sources within a food chain, but many of the predacious animals, which can consume many types of prey, may participate in several food chains. Thus natural populations in diverse environments tend to be organized into complex food webs, instead of consisting of a large number of independent food chains. This intricate association of plants and animals is called a natural community. (*See* ECOLOGY, ANIMAL.)

The diversity typical of many natural communities has two important consequences. First, mixed stands of vegetation often have relatively stable populations of animals. For example, in the mixed hardwood-hemlock forest of Michigan there has been no evidence of serious insect damage for 300 years and less than 5% of the insect species are conspicuous at any one time. Second, diverse communities tend to ward off invasion by foreign species. How this is accomplished has not been established; perhaps all potential sources of existence are being utilized and an invader must partially or completely displace a native species. The stability, both qualitatively and quantitatively, of populations in a given community is not complete, of course, because the abundance of a species fluctuates, sometimes violently, and a new species will become established occasionally. But a community has typical kinds of plants and animals, each of which is present in typical average abundance—some are rare, whereas others are common or even dominant. These observations of relative stability have led to the concept of the balance of nature. The particular forces that determine this balance are a matter of intensive research and great controversy, but it is clear that the size of a population is determined by the physical and biotic agencies operating on the species.

Disruption of Nature.—Some natural processes, the occurrence of chance catastrophes, and particularly the systematic activities of man have so greatly modified the diversity of natural communities that in many areas of the earth the vegetation has become much more uniform. The tendency toward monocultures of crops and the development of agricultural practices have simplified community structure—that the simplification is relative is shown in alfalfa fields in California where over 600 species of arthropods have been found—and have separated and shortened food chains with two important consequences. First, more uniform vegetation is rather easily invaded. Many insects are imported with their traditional host plants; in a favourable climate and in the absence of their natural enemies, they often become established and prosper. Most major pests of agricultural crops are of foreign origin, and have become economically important only when introduced elsewhere. In other cases the production of new crops over large areas resulted in the transfer of hitherto innocuous insects and diseases from scattered native plants to this new and abundant source of food. (*See* the article COLORADO POTATO BEETLE for a description of how a pest may arise and spread.) Second, with more uniform plant cover some phytophagous species increase and fluctuate in abundance. As a plant species becomes dominant it is increasingly subjected to attack by its enemies; in contrast to the mixed hardwood-hemlock forest in Michigan, pure stands of hemlock, aspen, balsam fir and pine were heavily attacked by individual species of forest insects.

The increase and fluctuation in the abundance of phytophagous species in simplified communities are also accentuated by two additional factors. First, weather modifies the susceptibility and nutritive value of crop plants to the attacking species, affects the survival and development of phytophagous species, and influences the development of the host plant and the phytophagous species so that the required food may be available in large amounts and in suitable condition at the right time in some years but not in others. In addition, since each of the cold-blooded animals in a food chain responds differentially to modification of its environment, a simple food chain is easily disturbed by slight changes in weather. Second, when a variety selected for crop production forms the uniform plant cover, it permits much greater rates of increase by plant feeders than do its wild counterparts; irrigation, cultivation and fertilization enhance still further this characteristic. With this type of host plant, slight modifications in the effectiveness of the biotic and abiotic factors that determine population growth can result in a marked increase in the abundance of the phytophagous species.

Kinds of Pests.—The numbers a potential pest must reach to be considered a serious threat to man vary from species to species and depend on many other factors; *e.g.*, a single mosquito that is a

vector of malaria is more dangerous than several leaf-eating larvae. Only a small portion of the animals living in any area are pests; *e.g.*, of the many thousands of insect species in the United States, only about 10,000 species, which attack about 1,000 species of plants, are of economic significance, and of this number less than 200 are considered major plant pests. Unfortunately, these relatively few species cause damage reckoned in billions of dollars.

Most pests are invertebrate animals; they include especially insects and mites, but also nematodes, snails and slugs. Microorganisms such as fungi, bacteria and viruses are here considered with pests even though they are usually thought of as agents of disease. Among the vertebrates many kinds of rodents, rabbits and hares and elk and deer are sometimes injurious to crops. And weeds are often strong competitors of crop plants. When pests are limited to a level of abundance at which their injury is unimportant economically they are said to be controlled. Control is used here in its economic rather than its ecological sense.

As arthropods and plant diseases constitute the chief threats to the welfare of man, the development of pest control has been directed, for the most part, on restricting as much as possible the abundance of these forms. This article deals, therefore, largely with the various methods used to control these pests and some results of control.

CHEMICAL CONTROL

Nature itself practises chemical control: certain plants bear poisons thought to provide some protection against damage by other organisms; animals contain antibodies that provide protection against invasion by foreign elements; and certain microorganisms produce substances (antibiotics) antagonistic to other microorganisms. Man, however, has carried chemical control to a far more effective and potentially dangerous extreme in devising compounds of exceptional potency.

Types of Pesticides

All pesticides are alike in blocking some metabolic process; however, they differ widely in composition, potency, mode of action, speed of effect and dosage required. They are often classified according to the type of organism that they are principally intended to control, as rodenticide, insecticide, acaricide (against mites and ticks), nematicide (against roundworms), herbicide (against plants), fungicide, etc.

Insecticides.—Insecticides are usually divided into several categories depending on their mode of action on the pest species; these categories are arbitrary since a given compound may fall into two or more classes.

Stomach poisons are used against insects such as caterpillars with biting mouth parts, and are toxic only if ingested. The toxic action of inorganics such as the arsenical (paris green, lead arsenate, calcium arsenate) and fluorine compounds (sodium fluoride, cryolite) and plant compounds (ryania, nicotine, rotenone) is thought to result from inactivation of oxidizing enzymes at the cellular level. These compounds require thorough application to be effective, and largely have been replaced by synthetic contact insecticides.

Contact poisons penetrate the integument of the pest and are used against those arthropods such as aphids that pierce the surface of a plant to suck out juices. The naturally-occurring contact insecticides are nicotine, developed from tobacco; pyrethrum, from flowers of *Chrysanthemum cinerariaefolium;* rotenone, from the roots of *Derris* species and related plants; and the petroleum oils. Although these compounds were originally derived mainly from plant extracts, the toxic agents of some of them (*e.g.*, pyrethrins) have been synthesized. These insecticides are usually short-lived on plants and cannot provide protection against prolonged invasions. They are, however, effective where infestations are of short duration, provided they hit the pests directly.

The synthetic contact insecticides are now the primary agents of chemical control, large numbers of them being developed annually. Their efficiency varies widely with such factors as the particular compound, the species of pest, the host plant and the weather; but in general they penetrate the organism readily (some also act as stomach poisons) and are toxic to a wide range of species. The development of a series of chlorinated hydrocarbons was begun with the discovery of the insecticidal properties of DDT in the early 1940s. Other examples of this series are BHC, with its isomer lindane; toxaphene; chlordane; and aldrin and its epoxide, dieldrin. Some of these compounds are very stable and have long residual action. They can be used in many situations but are particularly valuable where protection is required for prolonged periods. Their stability also enables them to be used in the soil against pests such as wireworms, cutworms and leatherjackets. Their toxic action is not fully understood but apparently they affect the nerve axon, leading to a disorganization of the nervous system.

A second series, based on the organophosphates, contains compounds such as parathion, TEPP, schradan, demeton, diazinon and malathion. Most of the organophosphorus insecticides are very effective against sucking forms such as aphids and red spider mites, but some of them also act against biting arthropods. Some are relatively long lasting (*e.g.*, parathion), others decompose rapidly (*e.g.*, TEPP). Several can be used systemically, *i.e.*, they are absorbed into a plant and later kill sucking insects feeding on the plant. Demeton, dimethoate, phosphamidon and schradan are examples of systemic organophosphorus insecticides. Absorption into the plant is achieved either by spraying the leaves or by applying solutions or granules impregnated with the chemical to the soil so that intake occurs through the roots. Warble flies developing in cattle can be killed by systemic organophosphates applied to the host. The organophosphorus insecticides are often metabolized by the insects into potent compounds such as malaoxon or paraoxon that inhibit the enzyme cholinesterase. This enzyme controls the level of acetylcholine, a compound necessary in the transmission of nerve impulses; excess acetylcholine disorganizes the nervous system. A second interpretation is that the insecticides inhibit the aliesterases instead. A third and more recent series of synthetics is the carbamate group which is also thought to act as anti-cholinesterases.

Fumigants such as hydrogen cyanide, naphthalene, nicotine and methyl bromide are toxic when they enter the respiratory system of the pest. These chemicals are used mainly for killing insect pests of stored products or for fumigating nursery stock. Methyl bromide, dichloropropane and chloropicrin are also used for fumigation of the soil, principally for the control of plant parasitic nematodes (*see* Fumigation).

Repellents repel insects rather than kill them. They are used against arthropods of medical importance such as mosquitoes, bloodsucking flies and chiggers; for example, dimethyl phthalate is the active principle of some mosquito repellents. Bordeaux mixture, lime, creosote and sulfur repel plant pests.

Chemosterilants inhibit reproduction of insect pests rather than kill them. The induction of sterility in flies and mosquitoes prevents rather than reduces outbreaks. The combination of a chemosterilant and an insecticide may be a means of overcoming resistant strains.

Fungicides.—Compounds used either to prevent or to stop the development of fungal diseases on crop plants are based on such chemicals as sulfur, mercury, copper or dithiocarbamate and thiuram derivatives. Most fungicides are protectants and must be applied before diseases develop, although organomercury compounds, for example, can be used to stop incipient infections of some diseases, provided they are applied within a day or two of the onset of infection. Fungicides usually have a broad spectrum of action, though a few are more specific; *e.g.*, dinocap and sulfur against powdery mildews. Systemic fungicides are at an early stage of development, and the compounds available are very restricted in their use; most of them are antibiotics, *e.g.*, griseofulvin and cycloheximide, but some synthetic compounds are being developed.

Herbicides.—Herbicides can be broadly divided into nonselective and selective groups. Examples of the former are sulfuric acid, sodium chlorate and the recently developed bipyridyls (*e.g.*, diquat). These will kill most vegetation with which they come into contact. More important in agriculture are the selective

herbicides, many of which are based on the substituted phenoxy acids or halogenated aliphatic acids; *e.g.*, 2, 4-D, MCPA and dalapon. The individual properties of these chemicals enable them to be used selectively, some to control broad-leaved weeds in plantings of cereals, others to control noxious grasses in broad-leaved crops. The triazines, ureas and carbamates can be applied to the soil around established plants or, more usually, prior to sowing annual crops; they control germinating weeds for prolonged periods. Selectivity in this case is due partly to the inherent resistance of certain crops to these chemicals but also to the placing of the chemicals, which are usually very insoluble, where they will not affect the crop seed sown deeper down or act on roots below the zone of herbicidal action.

Other Pesticides.—Examples of pesticides used against other groups of pests include the anticoagulant warfarin in baits for the control of rodents and antibiotics for some animal diseases. And, of course, other substances are mixed with the pesticides in order to apply them or occasionally to enhance their effectiveness.

See ENTOMOLOGY: *Applied Entomology: Principles of Insect Control;* SPRAYS AND DUSTS IN AGRICULTURE.

BENEFITS AND DETRIMENTS

Effectiveness.—With the advent of the newer synthetic pesticides the control of arthropod pests in particular became much more effective. In some cases infestations of pests that were accidentally introduced into new areas were quickly and completely eliminated; in many other instances populations of target insects were reduced by as much as 99%. These new chemical control measures had a constantly increasing effectiveness in preventing crop losses, raising quality of produce, lowering costs of production and improving both the health and welfare of man and animals. In addition, pest control resulted in more stable levels of production. But it became apparent that some difficult problems associated with the use of wide-spectrum pesticides were arising.

The number of plant-feeding arthropods developing on uniform vegetation, while varying with the crop in question, is relatively small. For example, about one hundred harmful species occur on unsprayed apple trees in England; the number of these species that are sufficiently abundant to be important economically, however, is only a small fraction of that number. Treatment with wide-spectrum chemical insecticides to restrict the few species that are of economic significance has often resulted in the few surviving species causing more serious damage than they formerly inflicted, and the abundance of some of the surviving species fluctuates widely from year to year. In addition, the significance of various species as plant pests alters over the years as the program of chemical control is changed. This close relation between pest significance and chemical treatment results from the differential effects of pesticides on the various species and from the development of resistant races in the species being controlled.

Imbalance in Populations.—In spite of heavy mortality at the time of treatment, use of pesticides sometimes results in a subsequent increase in the density of the pest against which the pesticide was applied. This phenomenon, called flareback, results from the incidental destruction of natural enemies that were partially successful in limiting the abundance of the pest population. Since it takes some time for the natural enemies to re-establish themselves and become effective, the pest, temporarily free of important natural restraints, often multiplies rapidly.

A second type of imbalance occurs among plant-feeding species that are more tolerant of pesticides than are their natural enemies. These plant feeders are normally of minor importance because they are controlled at satisfactory economic levels by parasites, predators and disease; but when a wide-spectrum pesticide kills these natural enemies the hitherto unimportant plant feeders are largely released from control, increase rapidly and become pests. For example, the use of mild sulfur fungicides, particularly flotation sulfur, to control apple scab fungus in Nova Scotia resulted in a serious outbreak of the oyster-shell scale insect: the fungicide was not toxic to the scale but eliminated its two natural enemies, the parasite *Aphytis mytilaspidis* and the predaceous mite *Hemisarcoptes malus.*

Other disadvantages of pesticides are the accumulation of poisons in the soil of regions treated repeatedly and the probability of killing bees and other pollinating insects. The differential mortality of a pest and its natural enemies can also result from some of the compounds that are mixed with pesticides in order to apply them. There is limited evidence that pesticides also tend to increase pest abundance by modifying the host plant, and by altering competition between two species of plant feeders.

Development of Resistance by Pests.—Resistance to the toxicity of pesticides is occurring constantly in pests of agricultural and medical importance through the normal evolutionary processes of genetic variation and natural selection. Although resistance was a problem before the development of the synthetic pesticides, it has been greatly accentuated since these compounds were introduced. The rate at which a species develops resistance is related in part to the intensity of the selection pressure, and the newer organic insecticides exert a much more powerful pressure. Selection of a strain resistant to one insecticide can result in a degree of resistance to a related compound (positive cross-tolerance) because the mechanism of toxicity is somewhat similar in both cases. A strain may become resistant to more than one class of insecticide so that it becomes increasingly difficult to limit its numbers. Resistant strains of a species, as in the housefly, may arise independently in many areas of the world; many of these races differ in their susceptibility to the kind and amount of pesticide. Once resistance has developed it tends to persist in the absence of the pesticide for varying periods of time depending on the type of resistance and species of pest; it will gradually decline but can be very quickly restored by renewed exposure to the pesticide. Resistance has also arisen by chance in strains selected for characteristics other than resistance.

The physiological bases of resistance lie in integuments or digestive systems that are not penetrated by the poisons, in extra fatty tissues that can store the pesticide, in enzymes that detoxify the poisons to compounds that can be eliminated, in excretory systems to eliminate the pesticide or its toxic intermediate, in behaviour patterns to avoid spray deposits, or in what is called general vigour. Of these, detoxifying enzymes are probably the most important; in many cases DDT is dehydrochlorinated to the harmless compound DDE by the enzyme DDT-ase, whereas in organophosphorus-resistant houseflies enzymes degrade the toxic metabolites malaoxon and paraoxon. The presence of these characteristics, particularly of the detoxifying enzymes, depends on gene mutations that change slightly the nature of the enzymes normally produced by the insect. Resistance is usually based on single-factor inheritance—the gene locus may vary from one strain to another—or more than one factor can be involved. Degrees of resistance in strains of a species may depend on a number of different alleles at a given locus. One encouraging aspect of the resistance problem is that some beneficial insects are immune to the chemical poisons.

Effect on Wildlife.—Pesticides also present hazards to wildlife. Birds, fishes and small mammals have been poisoned by pesticides used to control insect outbreaks. The pesticides are passed up the food chains from herbivores to carnivores, in the process their concentration often being increased. The effect of insecticides on wildlife involves a number of factors, such as toxicity and persistance of a given compound, stability as it is transferred up the food chain, type of vegetation in which it is applied and species of wildlife. The chlorinated hydrocarbons aldrin, dieldrin, endrin and heptachlor are very toxic to birds and small mammals, but DDT when applied at low dosages apparently does not result in significant mortality of these higher animals. Fishes, however, have been affected by DDT even at the low rate of 0.5 lb. per acre; both the young fish and the aquatic insects on which they feed are highly susceptible. A single spraying has reduced brook trout and aquatic insect populations significantly but in about one year most species recovered. Young salmon, fry and parr, are quite susceptible, and repeated annual spraying greatly reduces their abundance and seriously disrupts the four-year cycle of this species. When spraying can be withheld the returning run and use of fish reared in hatcheries will compensate to a large extent for the excessive mortalities. Some fish may be able to develop re-

sistance to pesticides; there is some indication that mosquito fish from water near fields with a long history of treatment with chlorinated hydrocarbons showed resistance to DDT when compared with fish from areas not exposed to insecticides.

Hazards to Human Health.—In view of the widespread use of chemical pesticides it is not surprising to learn that compounds like DDT form part of the human diet. Drainage into major rivers has carried traces of pesticides so that some rivers contain about 0.2 p.p.m. (parts per million) of DDT. The residues may remain on the surface of food, be absorbed into the waxy covering of fruit and vegetables or contaminate such products as milk and cheese. From dietary sources an average-sized person in the United States in the mid-1960s contained in his body tissues about 7 p.p.m. DDT. The continued accumulation of organic pesticides in the human body is to be considered extremely undesirable, and, beyond a certain debatable limit, dangerous to health. As a means of lessening the possibility of damage to man, an acceptable daily intake of each pesticide residue, based on a lifetime consumption for man, has been established in the U.S. When these limits are not exceeded there is little danger of acute or chronic toxicity. In the case of exceptionally dangerous compounds, including carcinogens (cancer-inducers) this limit is zero; *i.e.,* no amount of such a substance is to be permitted to accumulate in body tissue. The dangers inherent in the application of pesticides can be overcome only if the directions for application of each compound are observed very closely and strictly adhered to. The possibility that exposure for long periods of time to very small amounts of pesticides and other chemicals of a modern industrial society (food additives, fallout, soot, etc.), may lead to illness or genetic change in man has become a matter of considerable controversy.

NONCHEMICAL CONTROL

Methods other than the use of pesticides have been employed successfully for a long time to protect some crops from plant pests. The expense of, and the problems arising from, chemical control methods in recent years have stimulated interest in nonchemical means of pest control, to minimize and supplement the use of modern pesticides. Most of these methods have an ecological basis.

Resistant Plants.—By selecting and breeding from the large pool of genetic variability in a species, races can be formed with characteristics desired by man; *e.g.,* the quality of wheat, the yield, time of maturing and resistance to disease such as rust have been selected by man. Similarly, plants resistant to attack by pests can be selected.

Resistance of plants to insects is based on three components: (1) physical characteristics of plants that make them undesirable to insects for oviposition, shelter or food; (2) antibiosis, in which the plant produces substances that adversely affect the biology of the insects; and (3) tolerance to insect attack. The resistance of the solid-stemmed wheats Rescue and Chinook to the wheat-stem sawfly is due to the inability of the larva of this insect to develop in anything but a hollow stem.

The selection of resistant varieties, one of the main methods of combating fungus and virus diseases of crop plants, must be unceasing to keep ahead of the development of races of the pest that can overcome a formerly resistant variety of crop.

Cultural Control.—Closely related to the development of resistant plants is the role of cultural practices in the control of plant pests, because resistance often depends on the conditions under which plants are grown. Crop rotation and cultivation are two classical means of reducing losses from plant pests. Even in areas where one crop is grown annually, agricultural practices may influence the abundance of pest species. For example, on the Canadian prairies an outbreak of the wheat-stem sawfly that began in the early 1930s and continued until the early 1950s was associated with below-normal rainfall throughout the 1930s and abetted by cultural practices such as farm mechanization, strip farming, surface tillage with preservation of stubble and the use of combine threshers and of early-maturing, rust-resistant varieties that were seeded early. In 1941 a cultural program based on trap strips, shallow tillage, rotation with immune or resistant crops and late seeding to escape infestation was established. In one area the infestation was reduced from 85% to 3% in one year. With insects of medical importance and, to some extent, agricultural and forestry importance, sanitation forms an integral part of many control programs.

Radiation.—A promising procedure in reducing populations of certain insect pests utilizes the sterilizing power of ionizing radiation. When rearing and treating techniques permit the production of insects in large numbers, sterile males with radiation-induced defects in sperm may be systematically released in numbers much greater than exist in nature. These males mate freely with native females but no progeny are produced. This process occurs more rapidly if the females by nature mate only once. The screwworm, which infests cattle, was eradicated in the southeastern United States by this method, and the technique is being tested on other insects such as the Mediterranean fruit fly, melon fly, oriental fruit fly, common malarial mosquito, boll weevil, oriental fruit moth and codling moth. Thorough knowledge of the biology of a pest is necessary before the chance of success can be determined.

In the laboratory it is possible to kill larval mosquitoes directly by high-frequency sound waves and to attract adult males to some form of trap by sound waves that simulate those produced by adult females. A more promising technique, however, is the use of sound to repel some insect species from field crops. As is well-known, bats use echolocation to find their insect food; some moths have evolved tympanal organs, or sound-sensitive receptors, that allow them to detect and avoid the sound-emitting bat. In one experiment a sound resembling that of a single bat was broadcast over experimental plots containing about 1,000 corn plants, and infestation by the European corn borer was reduced by 50% to 60%.

Transfer of Natural Enemies.—Most of the major pests of agricultural crops in North America have been imported accidentally and without their complement of natural enemies; once established, they often became more destructive than they were in their native range. In order to reduce many of these species to the level of abundance prevailing in their native environments, their natural enemies have been sought out, imported and released on that continent.

Imported enemies established in one area can be passively carried to other areas from which they might otherwise be barred by natural geographical barriers. Native pests may be spread into new areas by transportation facilities, or the distribution of a native species may be extended by the spread of crops to new areas. Their natural enemies may have to be artificially spread to provide a check on the pest populations. Occasionally native parasites become established on an imported pest. This and other natural methods, often collectively called biological control, employ living organisms as the control agents.

Until recently biological control relied largely on the use of parasites and predators. In the mid-1950s in the United States about 95 species of imported parasites and predators became established and about 390 failed to become established when used against about 77 species of pests. In addition, an attempt was made to extend the distribution of natural enemies already present or to increase their effectiveness by mass colonization or other means against another 14 species. Only a small portion of the important agricultural pests have been fully controlled by this method; most attempts have produced no measurable reduction of pest numbers. In Canada natural enemies were used against 11 crop and 36 forest pests; about one dozen pest species are considered to have been successfully controlled. Many other attempts have been partially successful in reducing crop damage.

Biological control has great potential for, when successful, it is self-perpetuating. With intensive research the use of natural enemies may become as predictable as the use of pesticides. The method is not without its complications, however. Introduction of a parasite for one pest may restrict the methods used to control another on the same host. In Kenya, for example, the coffee mealy bug, *Planococcus kenyae,* is well controlled by the parasite *Anagyrus kivuensis,* introduced from Uganda. The parasite is, however, very susceptible to the persistent insecticides (*e.g.,* DDT) that are used to control the bug *Antestiopsis lineaticollis* in the

same area. Resort must therefore be made to malathion or pyrethrum, which are of short persistence, rather less effectiveness and higher cost.

Microorganisms such as viruses, bacteria, fungi, protozoa and nematodes are important controlling agents in natural populations; some of these agents (*e.g., Bacillus* species) have been used with outstanding success in the control of insects of forest, turf and pasture. Moreover, they have the potential of being mass-produced in the laboratory and sprayed on field crops like an insecticide; they are usually harmless to man and plants; they are not affected by most insecticides; and they may greatly reduce pest numbers without seriously affecting the natural enemies.

Highly host-specific phytophagous insects have been used to solve some serious weed problems. Control of weeds refers not so much to the eradication of a pest plant as to the reduction of the species to an unimportant status. Insect enemies adversely affect the competitive ability of the pest plant so that other, more desirable vegetation becomes dominant. Weeds such as *Lantana* species, *Opuntia* species, St.-John's-wort, *Clidemia hirta*, and *Cordia macrostachya* have been reasonably controlled by introduction of certain plant-eating insects in various parts of the world.

Additional Methods.—Traps in various forms have long been used both to sample and to destroy pest populations. Some insects, attracted to particular odours, are drawn to traps to be killed by poisoned baits or merely to be collected and destroyed. Because males of some species are attracted from great distances to virgin females, sex attractants are being developed for use in such traps. The sowing of certain crops to receive, because of location or early appearance, the main oviposition of a pest species is a familiar agricultural practice.

The application of high frequency electric fields to the disinfestation of cereal products has had some success, but has not been developed extensively because insecticides and fumigants are readily available, highly effective and easy to apply. The manipulation of the environment through use of electropotential fields is just beginning to receive attention.

INTEGRATED CONTROL

The control of plant and animal pests has depended mainly on the use of pesticides because these products have been easy and economical to apply and have shown immediate, observable and highly satisfactory results initially. The widespread and persistant use of chemicals, however, has resulted in the development of a number of serious problems, which, with the advent of the synthetic contact insecticides have been greatly accentuated. The nonchemical methods of control have had spectacular successes in many individual instances but none of them has provided a general solution to the problem. Since chemical control is essential in many cases, it seems advisable to maximize its benefits and minimize its defects through carefully designed preventive programs combining pesticide application and biological control methods. This approach, called integrated control, has been receiving considerable attention as a promising means of maintaining pest populations at a level below which they are economically significant.

Requisites.—Integrated control depends on the fulfillment of several requirements. First, a detailed study of ecological relationships must be undertaken. Although only a few species are initially of economic importance in any given area, the entire complex or community of organisms, crop, weeds and environment is considered as a unit, because one species cannot be treated without affecting the others. It is therefore necessary to determine the species present in a community and something of the interactions between them. Since some natural enemies maintain their prey at low levels of abundance, whereas others are relatively ineffective, desirable relationships must be identified and fostered. Furthermore, since the interactions between species are greatly modified by environmental factors such as temperature, humidity, soil and crop, the resultant abundance of species will vary from one geographical area to another and to some extent from one year to another in the same area. Quantitative ecological surveys and analyses are constantly required.

Second, it is necessary to be able to predict the level of abundance at which economic injury will occur and to use repressive measures only when this level is approached. This level will vary with the species of pest, the crop attacked, the part of the plant attacked, and with cultural and environmental conditions. Control measures should be aimed only at reducing a pest population below economic levels; some pests must be allowed to survive to support a continuing population of natural enemies. When the permissible level of damage is very low, as in pome fruits (apple, pear, quince), control based on ecological principles is very difficult; but when higher levels of damage are acceptable, natural enemies may provide adequate protection and hence can be integrated with pesticide applications.

Third, pesticides should be as selective as possible, both from a physiological and ecological point of view. A pesticide is selective physiologically when it normally kills only certain broad groups of species. In Nova Scotia replacement of the mild sulfur fungicides by a fungicide such as ferbam re-established control of the oyster-shell scale because the latter pesticide was not detrimental to the scale insect's natural enemies. Stomach poisons or contact insecticides coated with materials that dissolve only when ingested are selective. Acaricides kill some mites but not insects. Microbial sprays, when effective, often attack individual species of insects. A given pesticide may be selective in only one situation or in one dosage; therefore the ecological conditions providing optimum effectiveness of pesticides must be determined.

Even the broad-spectrum pesticides can be used in a manner that makes them more selective. If possible damage by a widely-distributed pest is predicted in some areas, those areas only might be treated. The pest species and its accompanying natural enemies will be destroyed in the area treated, but, over-all, the parasite-predator complex will be maintained. If the natural enemies are mobile, they should be able to move into the treated areas and prevent flareback. A degree of selectivity can be achieved by applying pesticides at a time when beneficial insects are elsewhere, or are protected in some way, as a resistant stage or in a sheltered place.

The success of timing can be greatly accentuated through the proper use of pesticides with short residual action; many highly toxic phosphates can be used against a pest when beneficial biotic agents are in resistant stages such as eggs or pupae. Another aspect of timing depends on behavioural differences between pests and their enemies. If pests rest or congregate in limited areas for short times, these areas only might be treated at the appropriate time, and widespread application thus avoided. In some cases selectivity can be gained by lowering the dosage of a pesticide; at low dosages some insecticides are extremely effective on certain pests but are not detrimental to all the pests' natural enemies. Systemic insecticides absorbed by the plant and translocated to the leaves are effective only against plant feeders such as aphids, mites and thrips; as a rule they are not harmful to the parasites and predators of those pests. Some insecticides, especially systemics, can be mixed in the soil out of reach of many natural enemies. Baits, seed treatments and attractants also localize the distribution of poisons.

Fourth, the role of nonchemical methods of control, particularly the use of natural enemies, should be augmented as much as possible. While the efficiency of parasites and predators is determined to a large extent by climate, which cannot be manipulated, some aspects of herbivore-carnivore interaction can be made more significant by agricultural practices. Suitable host material may not be available throughout the year because of dry periods, for example, hence natural enemies may be greatly reduced. When conditions are favourable to the return of the pests, there is a significant time interval before the parasites and predators recover their numbers; during this period the pest population can expand uninhibited by natural enemies. Food for the natural enemies has been provided in some cases by planting alternative crops that support the pest or other hosts or prey; thus the supply of natural enemies is maintained and is available when needed. Adult parasites of many insect pests often require a feeding of nectar or pollen before they can oviposit; growing suitable flowering plants to supply these needs may increase their ability to re-

produce. Pollen is a substitute food of some predators; by providing this type of food the development of larval stages could be aided and dispersal of adults inhibited or directed. The provision of nesting sites also increases the density of beneficial predators such as birds and wasps.

In some instances the complexity of a community is deliberately increased on the assumption that greater complexity will result in greater stability of populations. As more and more plant feeders are incorporated into the system the number of generalized carnivores is greatly increased. If these carnivores migrate onto crop plants when they are infested with pests the predation of the pest population is greatly enhanced. Such complexity can be developed by sowing cover crops in orchards or maintaining hedgerows or other natural habitats within and bordering agricultural areas.

Deficiencies.—In spite of the great progress that has been made in developing integrated control programs, the approach has not been entirely satisfactory. One pest species may be difficult to control and so require a highly toxic broad-spectrum insecticide. In Nova Scotia the codling moth has one generation per year and can be controlled adequately by ryania, a relatively innocuous insecticide; but in other areas, with two or more generations per year, more toxic poisons are required. Natural enemies are not always available in sufficient numbers at the right times and are usually more effective in permanent rather than seasonal crops. Although a pest may be susceptible to low dosages of a highly selective insecticide, residues of this compound may be very dangerous to other organisms, including man, and therefore a more broadly toxic pesticide with shorter residual effects must be used. Integrated control often requires professional calibre supervision. And finally, integrated techniques are sometimes more costly than simple chemical control measures.

PROSPECT

It is impossible to tell what progress will be made in the development of highly specific pesticides. The number of pests in existence and the prohibitive cost of developing and producing a separate compound for each of them would seem to limit specificity to groups of arthropods. It is interesting to note in this connection that DDT was the first of the newer synthetic contact insecticides and yet it is still, in all probability, the most satisfactory pesticide when all aspects of its use are considered. Broad-spectrum pesticides are still required in some cases even though it is recognized that they represent a threat to the welfare of wildlife and possibly to man. In spite of detailed precautions in the applications of pesticides some side effects are to be expected. A course of moderation must be followed between the desired degree of control of pests and the deleterious effects that can be permitted on other organisms. The effects of chemicals on the whole ecosystem can only be assessed by the combined judgment of those interested in pest control, wildlife and human health.

The management of communities in the short term is concerned with quantitative variations in population densities of the numerous interacting species. This field of population ecology deals with the properties of and interactions between the species involved and how these interactions and properties are modified by geography, weather and, of course, pesticides. Inasmuch as each species has an enormous pool of genetic variability on which natural selection can act, there is a great amount of variation possible in the properties of species. The management of communities in the long term is concerned, therefore, with the qualitative changes in properties of species that control measures induce. It is important that control measures do not spawn super pests but leave us with populations that we can control. The top twelve inches of soil, and the plants that it supports, are our primary asset; this resource must be preserved at all costs.

(T. BU.)

PETAH TIQVA (PETAH TIKVA, "the gate of hope"), a town in Israel 7 mi. N.E. of Tel Aviv-Jaffa. Pop. (1961) 52,771. Lying in the plain of Sharon, it is one of the oldest Jewish agricultural settlements, first planted in 1875 by Jews from Jerusalem, and in 1882 resettled by a pioneer group from Russia. The settlement was once famous for its orange groves but it was invaded by industry; it produces textiles, chemicals, asbestos, paper, furniture and processed foods. Citrus groves and vineyards still flourish along the nearby Yarkon (Yarqon or Auja) river. The municipal garden has been the settlement's centre since the foundation of the village. The town has many schools, particularly for the fundamentalist section of the Jewish population. A short distance northeast are the ruins of the ancient city of Antipatris. (No. B.)

PÉTAIN, (HENRI) PHILIPPE (1856–1951), French army officer, the marshal who was chief of state from 1940 to 1944, was born on April 24, 1856, at Cauchy-à-la-Tour in the Pas-de-Calais. He was trained as a professional soldier at Saint-Cyr and at the École de Guerre and filled the various staff posts until 1914. When World War I broke out he was already 58, had not served outside France and had known no active service. Yet, in conflict with the prevailing staff theories of the need to maintain the offensive at all costs, he had evolved views of his own about the value, in modern warfare, of defensive strategy provided that infantry were supported by the coordinated fire power of artillery. These were to prove correct once the war in France had become one of attrition.

Pétain was put in command first of an infantry brigade, then (on Oct. 25, 1914) of the XXXIII Army Corps in Artois. He distinguished himself during the offensive near Arras in May 1915, and in June was given command of the 2nd Army as a full-ranking general. In 1916, when the Germans opened the attack on Verdun, he was given the task of stopping it at all costs. He showed skill and energy in organizing, deploying, and supplying his forces, and although the operation cost France about 350,000 men he held Verdun. This made him a popular hero, and he was appointed chief of the general staff in April 1917 and commander in chief on May 15, to succeed Gen. R. G. Nivelle. The morale of the French troops had deteriorated, and it became his special task to stop mutiny. By a combination of repression and reform of grievances, he again succeeded, so that the French Army was ready to meet the final German offensive of 1918. After March 1918, with Ferdinand Foch as generalissimo to coordinate French, British, and United States forces, Pétain was in charge of the operations assigned to the French armies. He

BROWN BROTHERS

PHILIPPE PÉTAIN DURING WORLD WAR I

prepared the offensives of August and September and was responsible for pushing the Germans back to the Ardennes.

Pétain's achievements during World War I were, therefore, great: and between the wars, as the veteran "saviour of Verdun" and as a marshal of France (from Nov. 21, 1918), he came to be regarded as a high military authority. In 1920 Pétain was appointed vice-president of the Supreme War Council and in January 1922 he was also made inspector general of the army. After the signature of the Locarno treaties, France reduced its armed forces considerably and decided to construct along the Franco-German frontier a powerful system of fortifications called the Maginot Line. Successive governments and public opinion alike welcomed a policy designed to be thrifty with French lives in the event of another war. But on the Franco-Belgian frontier a more offensive strategy in case of German aggression was envisaged.

Pétain resigned his post on Jan. 1, 1931; but as minister of war in Gaston Doumergue's short-lived government (February–November 1934), he demanded and partly obtained some increase of defense expenditure in order to supply French forces with modern equipment.

During the period of Popular Front government in 1936, Pétain made no secret of his contempt for parliamentary institutions, of his antipathy to Socialist ideas, or of his preference for dictatorial regimes which brought strength and prestige to their countries. In March 1939 Premier Édouard Daladier appointed Pétain ambassador to Spain. When World War II broke out he was, at the age of 83, a natural focus of hopes for those who believed that the strong government needed for war might be used to overthrow the parliamentary regime of the Third Republic.

The rapid collapse of the French forces in 1940 was, in most respects, the consequence of the outdated principles on which they had been organized and of the lack of mechanized equipment needed to meet the superior weight and mobility of the German Army. In the moment of defeat, France turned to the veteran marshal, whose name still represented victory although his attitude had long been defeatist. In May the premier, Paul Reynaud, recalled him from Spain, and on June 16 Pres. Albert Lebrun asked him to form a new ministry. His task was, amid conditions of almost complete disorganization and military defeat, to make a speedy armistice with Germany. This he accomplished by June 22; and two days later he completed a similar convention with Italy. By the terms of these armistices his government was left in charge of the French fleet and colonies and was allowed to maintain an "armistice army" of not more than 100,000 men at home. France was divided into two zones: the northern part and the Atlantic coastline remained under German military occupation; the southern part and the Mediterranean coastline were under the direct administration of the French government. On July 10 the National Assembly, specially summoned at Vichy to ratify the terms of the armistices, granted Pétain emergency powers until a "new constitution" could be promulgated. (*See* FRANCE: *History*.) He made himself "chief of state," with Pierre Laval as his first premier.

From July 1940 until the liberation of France in 1944, Pétain served as chief of state for the governments of Vichy; but, in face of German restrictions, he did not promulgate a new constitution. He became the object of a cult and of much adulation. His aim was to keep France out of the war and to hold Germany as closely as possible to the terms of the armistice which, when Hitler failed to defeat Great Britain and became deeply engaged in the U.S.S.R., proved increasingly favourable to France. But this involved him in a certain amount of active collaboration with Germany, and after 1942 the pressure of German demands on French labour and supplies intensified. In February 1941 Adm. Jean Darlan replaced Laval as premier; but Laval returned to power in April 1942 and remained the real ruler at Vichy until it collapsed. It seems probable that because of senility and illness Pétain ceased to understand fully what was happening, and much was done in his name of which he was unaware. Yet, by remaining in office even after the ardent collaborationists assumed power at Vichy in January 1944, he became implicated in responsibility for their betrayals of French national interests. Pétain was arrested by the Germans on Aug. 20, 1944, and taken by them to Belfort and thence, in September, to Sigmaringen in Germany; but he voluntarily returned to France in April 1945. For his whole behaviour after 1940 he was put on trial by the provisional government under Gen. Charles de Gaulle and, on Aug. 15, 1945, a High Court of Justice, by 14 votes to 13, sentenced him to military degradation and death. The sentence was changed to life imprisonment. He was imprisoned first at Portalet, then on the Île d'Yeu in a fortress, whence, after prolonged illness, he was moved to a villa in Port-Joinville a month before his death. He died at Port-Joinville, Île d'Yeu, on July 23, 1951, an acutely controversial figure in French politics: while many regarded him as a traitor, others idolized him as a patriot who had "stood by a stricken France" and had sacrificed himself in its cause.

PETALITE, a mineral species consisting of lithium aluminum silicate, is an important source of lithium (*q.v.*), the lightest metallic element. It was discovered in 1800 as cleavage masses in an iron mine on the island of Utö, near Stockholm, where it is associated with lepidolite and spodumene, also ores of lithium, and tourmaline. It is mined in Southern Rhodesia, in the trust territory of South West Africa, South Africa, and in Australia. In the United States it occurs in Maine, Massachusetts, and Wyoming.

The formula of petalite is $LiAl(Si_2O_5)_2$. In form, the monoclinic crystals approach spodumene (*q.v.*), which is also a lithium aluminum silicate with the formula $LiAl(SiO_3)_2$. There is a perfect cleavage parallel to the basal plane, and the mineral usually occurs in platy cleavage masses; because of this it was named from the Greek *petalon* ("a leaf"). The hardness is 6.5 and the specific gravity 2.4 (that of spodumene being 3.16). The mineral is colourless or occasionally reddish, varies from transparent to translucent, and has a vitreous lustre.

PETER, SAINT (SIMON PETER) (d. *c.* A.D. 64), the foremost of the 12 apostles chosen by Jesus Christ, a leader of the early church and traditionally the first bishop of Rome.

Peter in the New Testament.—Little is known of Simon Peter's life before he became a follower of Jesus. He came from Bethsaida in Galilee, a partially Greek-speaking area, which accounts for the fact that his name Simon is also found in the Hebrew form Simeon (Acts xv, 14 and II Pet. i, 1). That he is called "uneducated" (Acts iv, 13) may only mean that he lacked the formal education of a rabbi. He was married (Mark i, 30; *cf.* I Cor. ix, 5) and helping his father and his brother Andrew in a small fishing business at Capernaum on the Sea of Galilee when he first met Jesus.

His Call.—According to Matthew and Mark, Jesus at the beginning of his ministry called Peter and Andrew from their fishing to follow him, promising that he would make them fishers of men. Luke's account omits Andrew and precedes the event with a miraculous catch of fish. According to John, Peter came to Jesus through John the Baptist's movement: Andrew, a disciple of John, was directed by John to Jesus, to whom he then brought his brother, and Jesus gave him the name Cephas or Peter ("rock"). Mark and Luke, however, assign this appellation to the first mission of the 12 apostles, whereas Matthew places it later, at Caesarea Philippi, where Peter acknowledged Jesus as the Christ. This new name is closely associated with the leadership of Peter.

The Leading Disciple.—Peter occupied an outstanding place among the apostles (*see* APOSTLE). He is named first in all lists of the 12, he was the most frequent spokesman among them, and together with the brothers James and John he formed the "inner ring" that alone witnessed Jesus' raising of Jairus' daughter from

the dead, his transfiguration and his agony in the garden of Gethsemane before his arrest. The disciples are referred to as "Simon and those who were with him" (Mark i, 36; Luke ix, 45), and Jesus commanded Peter "strengthen your brethren" (Luke xxii, 32); the authenticity of this text as the genuine words of Jesus has been disputed, but it at least shows that the early church believed Peter to have held a unique place among the disciples. After Peter's confession at Caesarea Philippi, Christ called him the rock on which he would build his church and said that he would give him the keys of the kingdom of heaven (Matt. xvi, 17–19). The authenticity of this text also has been disputed, and it is discussed further below. The risen Christ's commission to Peter to shepherd his flock clearly gives Peter a position of leadership (John xxi, 15–19), though elsewhere in the Fourth Gospel the unidentified "beloved disciple" somewhat modifies Peter's pre-eminence. A further outstanding point is that Peter was the first to see the risen Christ (Luke xxiv, 34; I Cor., xv, 5), whom he had denied three times before the crucifixion.

The Early Church Leader.—After the ascension of Christ, Peter took the lead at once, as related in the Acts of the Apostles. He initiated the election of Matthias as the 12th apostle in place of the traitor Judas Iscariot, and after the descent of the Holy Spirit at Pentecost he interpreted this experience, "standing with the eleven," to the assembled Jews. He took the active part in healing a cripple at the gate of the Temple, his companion John being a mere lay figure. He was treated as leader of the group by the Sanhedrin, which imprisoned him and John, releasing them the next day with a caution. Peter pronounced sentence on the deceitful action of Ananias and Sapphira; with John he mediated the Holy Spirit to the converted Samaritans; and on the same occasion he rebuked Simon Magus for trying to buy spiritual gifts with money.

Peter traveled also to other parts, including Lydda (Lod) and Joppa, where he healed the sick. While at Joppa he was summoned to Caesarea by a Roman centurion called Cornelius who had been told by an angel in a vision to send for him. Peter meanwhile had also had a vision which included a command from heaven not to call common what God had cleansed. He immediately went to Caesarea, where he preached to Cornelius and those with him, and baptized them though they were gentiles. Peter was thus the first to admit gentiles as well as Jews to the church, an action which he afterward successfully defended before the apostles in Jerusalem.

Peter and Paul.—Although the historicity of Acts is disputed by some scholars, the substantial correctness of its information about Peter's position is borne out by the indisputable testimony of Paul's Epistle to the Galatians. Asserting his independence of human authority, Paul says that on his first visit to Jerusalem his chief purpose was to see Cephas, which shows that Peter was at that time the leader of the Jerusalem church. On the occasion of Paul's visit 13 or 14 years later, however, the position was rather different. Paul conferred with James (the brother of Jesus), Peter and John, three who "were reputed to be pillars" (Gal. ii, 9), and at the so-called apostolic council in Jerusalem James is again named first and takes charge, while Peter is the leader of the mission to the Jews, no doubt run mainly from Jerusalem.

Paul goes on to refer to another occasion in Antioch, a mixed community where the problem arose of Jewish and gentile Christians eating together. On a visit to Antioch Peter at first ate with the gentiles, but after the arrival of a delegation from James in Jerusalem he withdrew out of fear, thus drawing upon himself an outraged protest from Paul. Paul clearly did not recognize any authority of Peter over himself and his work and claimed the decision of the "pillars" as justifying his attitude.

The New Testament gives little later information about Peter. After being imprisoned by Herod and miraculously released "he departed and went to another place" (Acts xii, 17). The only further mention of him in Acts is at the Jerusalem council, where he supported the admission of gentiles to the church without circumcision (Acts xv, 7–11). He may have visited Corinth, where a party owed allegiance to him (I Cor. i, 12). For the two New Testament epistles ascribed to Peter, *see* PETER, EPISTLES OF SAINT.

Peter the Martyr.—That Peter was martyred is strongly suggested by the words addressed to him by Christ: "When you are old, you will stretch out your hands, and another will gird you and carry you where you do not wish to go" (John xxi, 18–19). I Pet. v, 1 may also hint at martyrdom, but II Pet. i, 14 is too late to count as independent testimony. If "Babylon" (I Pet. v, 13) is interpreted as referring to Rome, then the First Epistle of Peter was written in Rome.

The best evidence for the place, however, is in the First Epistle of Clement written in Rome *c.* 96: "Let us set before our eyes the good apostles: Peter, who because of unrighteous jealousy suffered not one or two but many trials, and thus having given his testimony went to the glorious place which was his due." This mention of Peter is placed just before a reference to Paul and the great multitude who "among us" suffered indignities and tortures and the "women persecuted as Danaids and Dircae." Paul was certainly martyred in Rome, and the others mentioned were martyred in the Neronian persecution. It is therefore very unnatural not to suppose that Clement is locating Peter's martyr death in Rome.

The tradition that Peter was in Rome is attested in other authors: Ignatius' epistle to the Romans implies that Peter, like Paul, held authority in the Roman church; the apocryphal Ascension of Isaiah refers to one of the 12 as being delivered into the hands of Beliar (*i.e.*, Nero, so Rome would be the place); the Roman episcopal lists make Peter the first bishop of the city; and Macarius of Magnesia quotes the Neoplatonist Porphyry as saying that Peter was crucified after shepherding the flock for a few months.

Perhaps the most interesting of the early evidence for Peter's stay in Rome is the information of Gaius, a Roman presbyter *c.* 200, quoted in Eusebius' church history: "I can point to the trophies of the apostles. If you go to the Vatican or to the Ostian road, you will find the trophies of those who founded this church." Eusebius apparently understood "trophies" as graves, though the meaning of the word is not entirely clear (but *see* below, *Shrines of Peter*).

In the 4th century St. Peter was commemorated with St. Paul on June 29, and the liturgy was celebrated in his honour not only at the Vatican shrine but also at a joint shrine for both apostles by a place called Catacumbas by the third milestone on the Appian way. The decline of the belief that relics of the apostle were located at this latter shrine caused the dedication of the church to pass to St. Sebastian (*see* below). The Roman calendar of 354 attaches the year 258 to this commemoration on June 29; possibly the year marks the foundation of the shrine on the Appian way. The reasons for the foundation remain obscure.

All this evidence taken together makes it highly probable that Peter did go to Rome and was martyred there. (Jo. Lo.)

Feast Days.—Peter and Paul are commemorated together on June 29, and Peter has other special feast days also. That of his episcopal throne (*cathedra*) is kept on Feb. 22, on which date was formerly celebrated his episcopal throne at Antioch, where he was traditionally bishop before he went to Rome. The festival of St. Peter in Chains on Aug. 1 is the dedication festival of the church in Rome of St. Peter in Chains (San Pietro in Carcere) reconstructed by Sixtus III. The commemoration of Peter's episcopal throne in Rome on Jan. 18 was abolished after 1960.

Apocryphal Material.—Various apocryphal documents dating from the 2nd century are attached to Peter's name. A "Preaching" (*Kerygma*), a "gospel" and an apocalypse have survived in fragments only. There is also the Acts of Peter, extant in fragments save for the part about his martyrdom, which contains the detail that his episcopate lasted 25 years, the legend (also mentioned by Origen) that he was crucified head downward, and the *Quo vadis* story. This relates that in time of persecution Peter was persuaded to save his life by flight, but on his way out of the city he met Jesus, whom he asked "Where are you going, Lord?" (*Quo vadis, domine?*); on receiving the answer "I am going to Rome to be crucified again" Peter instantly returned to Rome and was martyred. (X.)

Primacy of Peter.—Peter held a leading if not the leading

position among the apostles during the ministry of Jesus. He received the surname "Rock," was the first to see the risen Lord and was at any rate the *de facto* leader of the early Jerusalem church. The nature and extent of his leadership and its origin in a commission from Jesus Christ needs to be examined. When the Third and Fourth Gospels were written, it was believed that he had been entrusted by Jesus with the functions of strengthening the brethren (Luke xxii, 31–32) and leading the flock (John xxi, 15–17). But the latter passage, though good evidence for the mind of sections of the church at the turn of the 1st century, has little claim to be regarded as an authentic utterance of Jesus. The saying in Luke is more likely to be authentic, but its language is imprecise.

Peter's claim to primacy turns mainly on the authenticity and interpretation of the crucial passage Matt. xvi, 16–19: in answer to Peter's exclamation "You are the Christ, the Son of the living God" Jesus said:

"Blessed are you, Simon Bar-Jona! For flesh and blood has not revealed this to you, but my Father who is in heaven. And I tell you, you are Peter, and on this rock I will build my church, and the powers of death shall not prevail against it. I will give you the keys of the kingdom of heaven, and whatever you bind on earth shall be bound in heaven, and whatever you loose on earth shall be loosed in heaven."

Non-Roman Catholic scholars have tended to deny that this is a genuine saying of Jesus and to assert that it reflects certain local rivalries in the early church at the time when the Gospels were being compiled. The objections alleged against authenticity are the absence of the saying from the parallel passages in Mark and Luke, the use of the word *ecclesia* ("church") and the contention that the idea of building or founding a church formed no part of Jesus' teaching. The first objection has force against the context of the saying but none against its genuineness. Matthew's extra material would not fit well into the episode as related by Mark, but it is Matthew's regular practice to insert into a Markan context material derived from another source and this may very well be a piece of good tradition. The objection to the word *ecclesia* has much weakened since it has been shown that the idea of the church is thoroughly Old Testament. The early Christian community believed that it was the true continuation of the "people of God" or at any rate the true "remnant" thereof, and there is no reason why Jesus, who certainly formed a community, should not have thought and spoken in this way. He often speaks elsewhere of the "flock." The conception of founding a church is difficult only if one accepts the extreme view of Albert Schweitzer that Jesus contemplated the immediate consummation of the Kingdom of God. But on any view that allows for an intermediate period there is no serious problem, and even the language of building and the image of the rock are deeply rooted in Jewish tradition.

The genuineness of Matt. xvi, 18 may therefore be accepted even if it is not in its right context. There is a close parallel to it in John vi, 38. Both halves of the statement "You are Peter [Aramaic *Kepha;* Greek *Petros*], and on this rock [Aramaic *kepha;* Greek *petra*] I will build my church" certainly refer to Peter. On this point the Roman Catholic exegetes are right, and Protestant reluctance to admit it has been due to fear that the whole Roman position would be conceded with this one point. Against this church of which Peter is the foundation rock the powers of death (literally, the gates of Hades) will not prevail. The church thus shares in Christ's conquest of death, the apostles being primarily witnesses of the resurrection and Peter first among them as such. The metaphor of the keys (symbol of the power of administrator of the household) indicates the authority to give a judgment of acquittal or condemnation which will be valid in the kingdom of heaven.

On the other hand, the belief of the Roman Catholic Church that the authority given to Peter is continued in and confined to the bishops of Rome is nowhere stated in or implied by the New Testament. That conclusion requires the assumption that Jesus meant the church to have a visible centre concentrated in one place and one person. Starting from that presupposition one can find this centre of unity in Rome. But one cannot find it in the New Testament or the apostolic church. In fact the citation of Matt. xvi, 18–19 in the interest of Roman claims is not found until the beginning of the 3rd century (*see* also PAPACY: *The Schism of Hippolytus.*) (Jo. Lo.)

Shrines of Peter.—The earliest recoverable liturgical tradition, established at least as early as the middle of the 4th century A.D., associates St. Peter with two specific sites in Rome: the Vatican hill and, in association with St. Paul, the still-surviving church of St. Sebastian beside the Appian way. The literary record is in detail corrupt and full of obscurities, but in both cases the fact of an association of some sort has been established beyond dispute by excavation.

St. Sebastian's.—The church of St. Sebastian, founded by Constantine I and originally known as the Basilica of the Apostles (*i.e.*, of Peter and Paul), was built over the remains of a Roman cemetery of the imperial age. Within this cemetery three successive phases can be distinguished: a series of burials in an abandoned pozzolana quarry, some of them as early as the 1st century A.D.; a formally constituted funerary area incorporating the remains of this early cemetery and including a group of typical 2nd- and early 3rd-century mausoleums; and, built over the filled-in remains of both earlier phases, a funerary precinct of the second half of the 3rd century, comprising a mausoleum and several dependencies, on the walls of which (the so-called *triclia*) were found numerous *graffiti* recording the partaking of funerary banquets (*refrigeria*) in honour of SS. Peter and Paul.

The *triclia*, which was certainly built after A.D. 239, was itself replaced early in the 4th century by Constantine's church, and the tradition of an association with the two apostles was not only reaffirmed in the dedication but was also placed explicitly on record by Pope Damasus (366–384) in a metrical inscription in which he recorded that Peter and Paul had "dwelt" there, though whether in life or after death he unfortunately did not make clear. The later tradition that their bodies had lain there for a time immediately after their martyrdom may well have no more substantial basis than the obscurities of Damasus' text; certainly attempts to find confirmation of it in the archaeological evidence carry no conviction.

More plausible is the theory, based on a 4th-century record of the establishment of a joint cult of SS. Peter and Paul in 258, that the 3rd-century mausoleum was that of a well-to-do Christian and that the remains of the apostles were translated to it for safety during the great persecution of Valerian. Another suggestion, based on the absence of the name of Pope Cornelius from the document that records its institution, is that this was a schismatic, Novatianist shrine, established in rivalry to the official cult places on the Vatican hill and beside the Ostian way. There can be no certainty. In either case it is clear that after the so-called Edict of Milan, which legitimized Christianity, the significance of the association with Peter and Paul dwindled, and the dedication of the Constantinian basilica passed in time to St. Sebastian, whose body lay in the adjoining catacomb.

The Vatican.—The archaeological antecedents of the great church of St. Peter's built by Constantine I on the Vatican hill are no less complex. That in building it he believed himself to be honouring the actual grave of the apostle is proved by the formidable difficulties, both moral and physical, which he was prepared to face in order to build it where he did, terraced out from a steep hillside and obliterating a large and predominantly pagan cemetery that was still in active use. Excavation, while refuting the long-held belief that the southern half of the church rested on the substructures of the circus of Gaius and Nero (the traditional scene of Peter's martyrdom), has shown that the circus was very close, just to the south of the church; it has shown also that the focal point of Constantine's basilica was a marble-encased shrine enclosing the remains of a structure that may confidently be identified as the "trophy" of Peter which Eusebius cites as having been a well-known Christian monument more than a century before.

It is uncertain whether this "trophy," a small tabernaclelike structure of superimposed niches rather awkwardly inserted into the outer wall of a 2nd-century mausoleum, marks the actual grave

of the apostle. It was not built before about A.D. 160, and whatever was contained within the lowest recess was long ago dispersed, probably in 846 by the Saracens. It is arguable that it was no more than a cenotaph, erected by the early church to commemorate Peter's martyrdom nearby. There are, however, substantial arguments in favour of its having marked an actual grave. The mausoleums of the 2nd-century cemetery replace and have largely obliterated a number of earlier roadside graves, some of them as early as the reign of Nero; the builders of the trophy went to great pains to build it at a particular place and on a particular alignment, as if determined to mark the location of some very precisely defined object; and there are structural features of the trophy itself and of the wall into which it is built which suggest that this object may well have been a body. Whether the human bones (said to be part of the skeleton of an elderly man of robust physique) that were found within an arched-up recess in the foundations directly below the trophy came from such a grave cannot be determined. (*See* also VATICAN, THE: *History*.)

The archaeological evidence may be summarized as follows: It has not been proved that this was the site of Peter's grave. On the other hand it has been proved that since about the year 160 this spot has been the object of continuous veneration, a veneration which early hardened into a firm conviction that this was in fact the burial place of the apostle. It has moreover been shown that the surviving features of the 2nd-century shrine are consistent with, and in several respects most readily explained by, the hypothesis that it marks the site of an actual burial, which was disturbed by the builders of the adjoining mausoleum and which the contemporary Christian community rightly or wrongly identified as that of Peter. Whether, a century after Peter's death, they had good grounds for their belief cannot be decided; but that the shrine which they erected became the centrepiece of Constantine's basilica and that, situated directly beneath the high altar of the present church, it has remained the subject of continuous veneration for more than 18 centuries is a demonstrable historical fact. *See* also APOSTLE. PETER, SAINT, OF ALCÁNTARA (1499–1562), Spanish Franciscan mystic, who devoted himself to the fostering of a severe form of Franciscan life, was born at Alcántara on the Tagus in the region of Extremadura. His father was Peter Garavito, a jurist, and his mother was Maria de Sanabria, both members of famous noble families. When he was 14 years old, Peter was sent to Salamanca to study philosophy and returned home at 16 to enter the Franciscan order. He was ordained a priest in 1524. Peter's efforts as a friar emphasized the penitential aspects of the life of St. Francis of Assisi rather than the other virtues of the saint. To carry out his desires, he wrote special instructions for those who wished to join him and founded convents, such as that of Pedrosa, unique for their isolation and discomfort, in Spain and Portugal. Later these friars, who came to be known as the Discalced or Alcantarine Friars Minor, spread to Italy, Germany and France. Peter carried on a spirited correspondence with St. Francis Borgia, St. Louis of Granada, Blessed John of Ávila, and, in particular, St. Teresa of Ávila, whom he aided in her reform of the Carmelites and whose autobiography remains one of the best sources concerning his life and spirituality. Peter is also the author of a treatise on prayer which has been translated into all the languages of Europe (English 1926). He died at Arenas near Avila on Oct. 18, 1562, and was canonized in 1669; his feast day is Oct. 19. (A. S. TR.)

PETER I THE GREAT (1672–1725), tsar of Russia from 1682 and emperor from 1721, was born in Moscow on June 9 (new style; May 30, old style), 1672, the son of Tsar Alexis by his second wife, Natalia Kirillovna Naryshkina. On the death of his elder half brother, Tsar Fedor III Alekseevich, in 1682, Peter was first acclaimed tsar; but after a *coup d'état* by the household troops (*streltsy*; *q.v.*) he was reduced to the position of co-ruler with his half brother Ivan V under the regency of the latter's sister Sophia (*qq.v.*). Though he and Ivan were crowned on July 5 (N.S.; June 25, O.S.), 1682, the sanguinary character of the *coup* affected him profoundly and left him with a traumatic hatred of the *streltsy*. Living at Preobrazhenskoye, near Moscow, he was able to enjoy greater freedom than would have been allowed him in the Kremlin. He did not shine in the schoolroom but excelled in outdoor activities. In 1689 he married Evdokiya (Eudoxia) Fedorovna Lopukhina and, through François Lefort (a Swiss soldier of fortune), came under the influence of the foreign quarter, a miniature replica of western Europe in Moscow. About this time, he became interested in sailing and shipbuilding. He played no active part in the coup carried out in his name in August 1689, whereby his tutor B. A. Golitsyn (*q.v.*) secured the deposition of Sophia. Ivan accepted Peter's supremacy, and Peter's interest in military affairs grew more and more professional between the time of his mother's death in 1694 and that of Ivan, which took place in 1696.

In 1695, when operations against the Turks were resumed at the request of Russia's Austrian, Polish, and Venetian allies, Peter laid siege to Azov, and captured it in 1696. In March 1697 he set out on a grand tour of western Europe to learn shipbuilding and to discuss unofficially further action against the Turks. After visiting Prussia, Holland, and England, he cut short his stay in Vienna on hearing of a new revolt of the *streltsy*. In June 1698, on his way home, at Rawa, he met Augustus II, king of Poland and elector of Saxony, with whom, in view of the Holy Roman emperor Leopold I's desire for peace with the Turks, he laid plans for an attack on Sweden's overseas possessions (*see* PATKUL, JOHANN REINHOLD). In Moscow, the rising having already been suppressed, he interrogated the *streltsy* and probably took a hand in the subsequent mass executions; on his orders the corpses of the rebels were hung outside the convent to which he had confined Sophia. Also in 1698, Peter, in conformity with Western usage, ordered his courtiers and ministers to shave off their beards, by tradition always left uncut; at the end of 1699 he reformed the calendar, fixing New Year's Day at Jan. 1; and in 1700 he ordered the town population to wear Western dress.

Peter's treaty of alliance with Augustus II had been signed on Nov. 21, 1699, completing the anti-Swedish coalition which was to begin the Northern War (*q.v.*); and in August 1700, immediately upon receiving the news of peace with Turkey, Peter attacked the Swedes in Livonia. After the Russian defeat at Narva (November 1700) he devoted most of his time to the conduct of the war, returning to Moscow each Christmas to attend to the most pressing domestic problems. Only from 1709 was he able to give these matters an increasing share of his time.

Early in 1710 Peter was occupied in St. Petersburg with the preparations for the wedding of his niece Anna Ivanovna to Frederick William, duke of Courland. This was the first of four important dynastic alliances arranged by Peter; the second was the marriage of his son Alexis (*q.v.*) to Sophia Charlotte of Brunswick-Wolfenbüttel in 1711; the third was that of his favourite niece, Catherine Ivanovna, to Charles Leopold, duke of Mecklenburg, in 1716; and the fourth was that of his daughter Anna Petrovna to Frederick Charles, duke of Holstein-Gottorp, in 1725. His own marriage to a Lithuanian maidservant, Marfa Skavronskaya (*see* CATHERINE I, empress of Russia), with whom he had been living from 1702, took place in February 1712.

Peter's plan to raise the Balkan Christians against the sultan involved him in war with Turkey in 1711 (*see* RUSSO-TURKISH WARS); before setting out on the ill-starred campaign, he established the senate as his collective deputy. In June 1712 he left Russia for nearly a year, spent mostly in the field in Pomerania and at conference tables in northern Europe. Also in 1712 he

transferred his family to St. Petersburg, founded by him in 1703. In 1714 he directed the naval operation at Hangö (Hanko), where the movements of the fleet under F. M. Apraksin (*q.v.*) were synchronized with the progress of the army against the Swedes on land. Early in 1716, he again went abroad for nearly two years. In June he joined a Russian squadron of galleys which put into Copenhagen in July in preparation for the abortive landing of the allies against the Swedes in Scania. October saw him in Mecklenburg and Havelberg, November in Hamburg, March 1717 in France, July in Amsterdam. In October 1717 he was back in St. Petersburg, ready to deal with his refractory son Alexis, who died in the SS. Peter and Paul fortress in July 1718 (*see* ALEXIS). In autumn 1721, he celebrated the Russo-Swedish Peace of Nystad in St. Petersburg and in Moscow with banquets, pageants, and fireworks; and on November 2 (N.S.; Oct. 22, O.S.) he assumed the title of emperor (*imperator*) of all the Russias. In the summer of 1722 he conducted an expedition against the Persians, which led to the conquest of Derbent in Dagestan and Baku in Azerbaijan.

Since childhood Peter had suffered from epileptic convulsions. In May 1724, already ill with strangury and stone, he attended his second wife's coronation in Moscow. At the end of the year, he ordered the execution of William Mons, ostensibly for peculation, in fact on suspicion of misconduct with Catherine. Peter died in St. Petersburg on Feb. 8 (N.S.; Jan. 28, O.S.), 1725, after catching cold while helping to rescue the crew of a stranded sloop.

BRONZE BUST OF PETER I CAST BY CARLO RASTRELLI THE ELDER IN 1723. IN THE HERMITAGE, LENINGRAD

Foreign and Military Policy.—Peter embroiled Russia in the Northern War without adequate preparation. It seems that his imagination was inflamed by the prospect of capturing the trade between East and West. An ice-free port on the Baltic would be the natural terminus of the two shortest possible trade routes leading across Russia, one from China by way of the "lakes and rivers of Siberia," the other from India, up the Indus, down the Oxus (the modern Amu-Darya, mistakenly assumed to fall into the Caspian), and up the Volga from Astrakhan. That this dream was not forgotten, even in the turmoil of the Northern War, is shown by the expeditions sent out by Peter. One went in 1715 to explore the region between the shore of the Caspian and Persia, another, in 1717, to Khiva to search for the waterway to India. There was also the expedition to the Central Asian steppes between 1714 and 1722; and finally in 1724 V. J. Bering was dispatched to investigate whether Asia and America were joined together at Kamchatka.

Though the siege and naval bombardment of Azov ended in its capture and the establishment of the fortress of Taganrog, the result was small in proportion to the outlay in men, money, and material and made Peter realize that Russia had much to learn about war (this was the principal reason for his journey to the west). On the other hand, by striking at Azov, Peter had both leaped ahead of the southward progress of the Russian frontier and made a breach in Turkey's defenses in the spot most accessible to him. But Azov was worthless so long as the outlet to the Black Sea was barred by the Turks. In trying to gain access to the Black Sea by pressing along the Prut and the Danube in the guise of deliverer of the Balkan Christians, Peter, assuming the mantle that the Polish king John III Sobieski had cut out for himself, pointed the way to the Balkans for his successors.

When, once Peter had failed to reduce Narva, it became clear that wresting Ingria from Sweden would not be a walkover, he devoted all his energies to saving a desperate situation. A capable pupil of the Swedes on land and of the British and Dutch on the sea, he completely reshaped Russia's army and created its navy. In addition to directing the strategy of the war Peter exercised personal control over recruiting, training, organization, and tactics. He was a pioneer of the modern recruiting system. From 1710 men were conscripted periodically from among the petty townsfolk and the peasantry, usually one out of 20 in a particular age group, for 25-year service in the army and the navy. In the preceding decade the infantrymen were issued flintlock muskets, basic units were reduced to a more manageable size, the proportion of cavalry was cut down to 38% of the total effectives, including the new dragoon regiments armed with muskets and capable of fighting on foot. The movements of the infantry formations in battle were made more varied and flexible; the cavalry was trained to charge at a gallop using sidearms. In 1707 the Russian cavalry under Prince A. D. Menshikov, deployed across Poland, successfully harassed the Swedes.

The strategic plan worked out by the war council and approved in 1707 by Peter consisted in fighting a limited war, withdrawing before the Swedish army while depriving it of supplies, and cutting its communications until circumstances became favourable for a decisive engagement. This came about in the Battle of Poltava, fought on July 8 (N.S.; June 27, O.S.), 1709. This battle, as well as the Northern War as a whole, the Russians won by their own exertions, and not, as is sometimes asserted, because of the mistakes made by the Swedes. Peter was in command only of an infantry battalion at Poltava, but the tactics devised by him, notably the use that he made of the redoubts, were later to receive high praise from the French marshal Maurice de Saxe.

In his conduct of the Turkish campaign of 1711 Peter was less skilful and less fortunate. The strategic plan was sound in theory but the organization proved deficient and the infantry showed itself incapable of repelling the onslaughts of the Turkish cavalry. On the Baltic, Peter's efforts to make seamen of the Russians and Russia a naval power were rewarded with success. Though Russian ships of the line did not fight any decisive naval battle, they gave indispensable support to the Russian galleys; *e.g.*, at the doubling of Hangö in 1714, after which the Russians were able to establish a base in the Åland Islands. Galleys were also used for the landings in central Sweden in 1719 and 1721 and as troop transports on the Caspian in the Persian War of 1722.

War was Peter's element and his favourite method of achieving his aims, but he recognized the value of diplomacy as its essential adjunct. He transformed the archaic ambassadorial office into a ministry of foreign affairs, an efficient instrument of policy consisting of such able advisers and negotiators as F. A. Golovin, G. I. Golovkin, B. I. Kurakin, A. I. Osterman (*qq.v.*), Y. V. Bruce (of Scots origin), and P. P. Shafirov. When faced with war on two fronts at the time of the Prut expedition he could fall back safely on this second line of defense. In the art of diplomatic deception, in making promises without meaning to keep them, for instance when he undertook to hand over Livonia to Augustus II, Peter was the equal of his rivals.

In the early phases of the Northern War the prestige of Russia was low and Russian diplomats were snubbed or ignored when offering or asking for good offices. After Poltava the situation changed radically, and within less than a decade Russia was recognized as a great power and Peter's descendants were considered worthy marriage partners for Western princelings. The appearance of 30,000 Russian troops in Mecklenburg in 1716 was the consequence of the marriage of Catherine Ivanovna. Likewise the agreements concluded in 1715 with Prussia and Hanover and supporting the claims of both these countries on the Baltic against Sweden were evidence of Russia's newfound strength.

Yet to some extent Peter's success defeated itself. Even his allies begrudged him Riga and suspected him of harbouring designs to extend his dominion along the entire eastern and southern Baltic coast from Finland to Denmark. In 1717, anxious to relieve Russia of an intolerable strain by ending the war with Sweden, Peter again resorted to diplomacy but failed in a personal effort to persuade France to reverse alliances by dropping Sweden for Russia. The Treaty of Amsterdam concluded with France in

August 1717 (to which Prussia was also a party) provided for French mediation and for the nonrenewal of France's subsidy treaty with Sweden. Peter had hoped for more and was considered to have suffered a diplomatic defeat; but even before the treaty was signed he was already in touch with Charles XII's diplomatic adviser, G. H. von Görtz, with a view to starting secret peace negotiations with Sweden. Though he antagonized George I of Great Britain by intriguing with the Jacobites, Peter skilfully exploited dissension in Sweden and in Poland, where he made common cause with Prussia over the question of the religious dissenters while preserving for himself the function of supreme arbiter in Polish domestic affairs.

Internal Policy.—The reforms of Peter the Great were a necessity imposed by the Northern War. Thus it came about that he had to perform the task of more than one monarch and generation, to prepare for war and to wage it at the same time. In the process he exhausted Russia and himself. The reform measures bear the stamp of his character: they were essentially practical, often experimental.

Peter insisted on each individual's serving the state to the best of his ability, with his person or his purse, as "money is the life-blood of war" and men, presumably, were its sinews. The civic chamber set up in 1699 was first offered to the townspeople as a form of self-government in exchange for doubling their tax liabilities. The division of the country into ten vast provinces in 1708–10 was conceived as a simplified means of tax-gathering. Each governor collected his portion and sent it directly to the department for which it was designated: the army, the navy, artillery, foreign affairs, etc. In a desperate effort to find the necessary funds, imposts, ingeniously devised by Peter's "profit-makers," were heaped upon every conceivable object; monopolies were established, commercial rights assumed by the state and leased to concessionaires; and the currency was debased.

Only after 1709 was Peter able to turn to more permanent and reliable methods of financing war. As the existing administrative organization was being bypassed, it fell into disuse and nothing was put into its place until in 1711 the senate was created to coordinate the work of the governors, the first phase in the creation of a new machinery of government. A census of the population was ordered in 1710 to provide a realistic basis for the collection of the tax on homesteads, but as it produced statistics far short of expectation, its results were ignored. Only the next census, carried out between 1717 and 1724, enabled Peter to impose a poll tax on all male peasants and petty townsmen. In Peter's last year this scarcely yielded enough revenue to cover the cost of the army and part of the navy. The poll tax was a great social leveler: for administrative convenience it fused various categories of peasants and semiurban vagrants into one vast class of serfs subjected to the local landowner who collected their tax, issued their identity cards (thus controlling their movements), and chastised them with the knout.

In addition to ready money for current expenditure, Peter had to find capital for investment in industry, the supply base of his armed forces. The class that provided capital was too small in Russia and was no doubt suspicious of the unpredictable ways of autocracy. Peter's persistent coaxing of private enterprise had little effect: it did not produce a Russian bourgeoisie any more than did the municipal law of 1721 granting a large measure of self-government to the guilds under the supervision of a chief magistrature. Characteristically, Peter demanded from the municipal magistrates unquestioning obedience alongside of initiative and self-reliance. While the primary object of the law of individual inheritance of 1714 was to prevent the fragmentation of estates, its subsidiary aim, which was to direct the disinherited sons into trade and professions after an initial period of state service, remained without practical consequences for the formation of a middle class. Its only immediate effect was the disappearance of the distinction between feudal estates and allodial or absolutely owned estates: henceforth both were the property of members of a single though not uniform class. Also in 1714 Peter replaced the periodic musters of the gentry by registration with the senate, where from 1722 all records of service were kept up to date by the chief herald. At the same time all defaulters were outlawed. Service was compulsory and began in the classroom: all adolescent nobles had to master the three R's, at one point under pain of not being allowed to marry. Promotion had to be earned by service in the ranks of the guards (including the Life Dragoons created specially for the sons of the old aristocracy) or, by those not born high enough, in other regiments.

Whereas the abolition of genealogical seniority among the boyars in 1682 under Fedor III (*see* BOYAR) had removed the bolts and bars from the door leading to the uppermost stratum of Russian society, Peter flung the door wide open to able men of obscure social origins; but once the emergency was over he slammed it behind them. In 1722 the whole of the privileged class, including the upstarts who had risen to high official positions, was organized into a hierarchy of three categories with 14 parallel grades, military, court, and civil, the status of those placed in the eight upper grades being hereditary. All promotion was by merit, and in theory all men who had proved their worth in the army, the civil service, and even in the magistracies qualified for admission to the privileged class.

Peter brought autocracy up-to-date by equipping it with an army and a bureaucracy and by putting in the place of its mystical aura the *raison d'état*—a development best illustrated by the case of his son Alexis. In one respect he carried it to new and extreme limits: in 1722 he took powers to appoint his own successor. But as Peter was physically unable to exercise the new prerogative in the hour of his death, it was arrogated by Menshikov, aided by the guards; and the latter exercised it again and again for the rest of the century. The guards, in fact, were in the van of the new class. Behind them, where the state servants and the boyars had been, stood a military and bureaucratic class separated from the mass of the people by a vast gap dotted with a mere nucleus of a middle class, productive of wealth but not of ideas. Together they made up a structure not far removed in its social polarity from that of Prussia or of Austria.

PETER II (1715–1730), emperor of Russia from 1727, was born on Oct. 23 (new style; 12, old style), 1715, the only son of the tsarevich Alexis (Aleksei Petrovich) and Sophia Charlotte of Brunswick-Wolfenbüttel. His mother died after giving birth to him; his father was put to death in 1718; and thenceforward the orphan was kept in the strictest seclusion. On May 18 (N.S.; 7, O.S.), 1727, however, according to the terms of the supposed last will of the empress Catherine I, he was proclaimed sovereign autocrat. His education was entrusted to the vice-chancellor A. I. Osterman. Prince A. D. Menshikov (*q.v.*), who lodged Peter II in his own palace on Vasilevski Island, had intended to marry him to his daughter Maria; but the scheme was frustrated by Menshikov's fall from power in September 1727. Peter then became a tool of the Dolgoruki family, who carried him away from St. Petersburg to Moscow. Crowned in Moscow on March 6 (N.S.; Feb. 24, O.S.), 1728, the young emperor was encouraged to indulge in thoughtless pleasures. He was betrothed to Catherine, a daughter of Aleksei Dolgoruki, but died of smallpox on the day fixed for the wedding, Jan. 29 (N.S.; 18, O.S.), 1730.

See K. Waliszewski, *L'Héritage de Pierre le Grand* . . . (1900).

PETER III (1728–1762), emperor of Russia during the first half of 1762, was born at Kiel in Holstein-Gottorp on Feb. 21, 1728, the only son of Charles Frederick, duke of Holstein-Gottorp, and of Anna, eldest surviving daughter of the Russian emperor Peter the Great. In December 1741 he was designated as successor by his mother's sister the empress Elizabeth, as soon as she was established on the Russian throne. On Nov. 18 (new style; 7, old style), 1742, he was received into the Orthodox Church, exchanging his original name of Karl Ulrich Peter for that of Peter Fedorovich and being proclaimed heir to the Russian throne. On Aug. 21 (N. S.), 1745, by order of the empress Elizabeth, he was married, in St. Petersburg, to Sophia Augusta Frederica of Anhalt-Zerbst, who took the name of Catherine Alekseevna (*see* CATHERINE II the

Great). He was physically less than a man and mentally little more than a child; she was of prodigious intellect and insatiable appetite for pleasure.

Having succeeded Elizabeth on Jan. 5, 1762 (N.S.; Dec. 25, 1761, O.S.), Peter not only expressed his intention to divorce Catherine but also displayed in ever increasing measure the oddest moods, arousing by his tactless folly the contempt of the court camarilla and of the clergy. Even his manifesto of March 1 (N.S.), 1762, which relieved the gentry of compulsory military service, did not mitigate hostile feelings.

Peter abruptly reversed Elizabeth's policy with regard to Russia's participation in the Seven Years' War (*q.v.*). He had not been on the throne for two months when he made pacific overtures to the king of Prussia, Frederick the Great, to whom he habitually alluded as "the king my master." His worship of Frederick resulted in a peace and then in an offensive and defensive alliance between Russia and Prussia; and all the territory won from Prussia by Russia during the preceding five years was restored to Frederick. A series of menacing rescripts were then addressed to Vienna, in which Peter threatened war unless Austria instantly complied with all Frederick's demands. Finally he quarreled with Denmark, and the Russian army received orders to invade Denmark by way of Mecklenburg. Before the actual collision took place, however, the army received news of the *coup d'état* by which Catherine succeeded to the Russian throne in her husband's place.

Peter, who had abdicated on July 10 (N.S.), 1762, was taken into custody at Ropsha, near St. Petersburg. A few days later, on July 17 (N.S.; 6, O.S.), he was killed in a brawl, through the connivance of his custodian, Aleksei G. Orlov, and other officers.

See R. N. Bain, *Peter III* . . . (1902).

PETER (PEDRO), the name of four kings of Aragon.

PETER I (1068–1104), king from June 1094 in succession to his father Sancho V Ramirez, conquered Huesca (1096) and Barbastro (1100) from the Moors of Saragossa (Zaragoza). He was twice married but left no children and was succeeded by his brother Alfonso I.

PETER II (1174–1213), king from April 1196, was the eldest son and successor of Alfonso II. He was an impulsive and brave warrior, but vain and incautious. He married (1204) Mary, lady of Montpellier, and thus greatly extended Aragonese power in southern France. Despite the violent objections of his subjects, he had himself crowned by Pope Innocent III in Rome and declared his kingdom a feudatory of the Holy See (1204). Peter, with other Spanish kings, took a prominent part in the victory over the Moors at Las Navas de Tolosa (July 16, 1212); but he then went to support his brother-in-law Raymond VI of Toulouse against the crusader Simon de Montfort in Languedoc. There he was killed in the Battle of Muret on Sept. 12, 1213. His son James I succeeded him.

PETER III the Great (1239–1285) became king in July 1276, on the death of his father, James I. In 1262 he had married Constance, heiress of Manfred, the Hohenstaufen king of Sicily; and after the revolt of the Sicilians in 1282 he invaded the island and was proclaimed king at Palermo, despite strong Guelph and papal opposition (*see* VESPERS, SICILIAN). His Sicilian enterprise was unpopular in Aragon, where an association of nobles and some municipalities, the Unión Aragonesa, forced him to grant a privilege not only confirming the Aragonese *fueros* but diminishing some of the crown's rights. In 1285 Philip III of France invaded Aragon to dethrone Peter, but was disastrously defeated. Peter, however, died in November 1285. His great stature and physical strength were famous. Among his children were Alfonso III of Aragon, James I of Sicily (II of Aragon), and Frederick III of Sicily.

PETER IV the Ceremonious (1319–1387) was born at Balaguer, the son of Alfonso IV, whom he succeeded in January 1336. He was the most cultivated of Spanish 14th-century kings. He was also an inveterate political intriguer whose ability to dissemble was notorious. Through his voluminous correspondence, the workings of his mind are far better known than those of any contemporary Spanish ruler. Having picked a quarrel with James III of Majorca, he reincorporated the possessions of the Majorcan crown, namely the Balearic Islands and Roussillon, by force into his own dominions (1343–44). He next crushed the long-standing pretensions of the Aragonese nobles by defeating the armies of the Unión Aragonesa at Epila (1348), thereafter displaying the extreme vindictiveness that he always showed when his authority was challenged. Peter had to contend with revolt in Sardinia throughout his reign; but he succeeded, by political and military means, in preparing the future reunion of Sicily to the Aragonese crown and was recognized by the Catalan Almogávares as duke of Athens and Neopatras in 1380.

The chief event of his reign, however, was the intermittent war (1356–66) against Pedro I of Castile. Urged on by France, and by his own ambitions, Peter underwrote Henry of Trastamara's claims to the Castilian throne in exchange for a promised cession of one-sixth of Castile. The war was disastrous to Aragon, which was saved only by the intervention of the mercenary companies brought from France by Bertrand du Guesclin. Henry of Trastamara failed to honour any of his promises to Peter, and after 1369 Charles V of France took no trouble to conceal that he preferred his alliance with Castile to that with Aragon. As a result, Peter now pursued a complicatedly neutral approach to the Hundred Years' War, with some bias in favour of the English. His last years were clouded by a quarrel with his heir, the future John I, who in 1380 married Yolande of Bar instead of the Sicilian heiress chosen for him by Peter and who then let himself become the tool of French intrigues against Aragonese neutrality.

Peter IV died in Barcelona on Jan. 5, 1387. He had been married four times. (P. E. R.)

PETER, king of Castile: *see* PEDRO the Cruel, king of Castile.

PETER, kings of Portugal: *see* PEDRO.

PETER I (1844–1921), king of Serbia from 1903 and of the Serbs, Croats, and Slovenes from 1918, was born in Belgrade on July 11 (new style; June 29, old style), 1844, the third son of Prince Alexander Karageorgevich and Princess Persida, née Nenadovich. He became heir after his elder brother Svetozar's death (1847) and was in Switzerland when his father abdicated (1858). Educated in France (at the Collège Sainte-Barbe in Paris, at Saint-Cyr and at the École Supérieure de Guerre in Metz), he was commissioned in 1867 as Lieut. Kara in the French Army. In the Franco-German War, he distinguished himself at Villersexel (Jan. 1, 1871), was awarded the Légion d'honneur and was taken prisoner by the Germans, but escaped by swimming the Loire. As Peter Mrkonich, he fought against the Turks during the Hercegovinian insurrection in 1875, but Austrian intervention compelled him to leave the insurgents' encampment in 1876. Later he went to Montenegro, where in 1883 he became an honorary senator; and on July 12 (N.S.), 1883, he married Zorka, first child of Prince Nicholas of Montenegro. When his wife died in 1890, he moved to Geneva.

On June 15 (N.S.; 2, O.S.), 1903, Peter was elected king of Serbia after the assassination of King Alexander, with whom the Obrenovich dynasty became extinct. Returning to Belgrade, he was sworn in and crowned on Sept. 21 (N.S.), 1904.

His lifelong experience, his liberal education, his study of John Stuart Mill's works (he had produced a Serbian translation of Mill's essay *On Liberty* in 1868), and his respect for constitutional traditions and parliamentary rules made Peter a strictly constitutional monarch, and he did much to promote the rapid political consolidation of Serbia after the upheaval of 1903. In poor health and advanced in years, Peter in June 1914 appointed his heir Alexander (*q.v.*) to be regent for him on the eve of World War I; but his stirring proclamations to his army and the visits that he paid to the trenches, notwithstanding his crippled condition, served to encourage the national resistance. He shared in the retreat across Albania (November–December 1915), being carried in a litter. At the end of the war he returned to liberated Belgrade and was proclaimed king of the Serbs, Croats, and Slovenes on Dec. 1, 1918. He died at Topchider, near Belgrade, on Aug. 16, 1921.

See R. Chambry, *Pierre Ier, roi de Serbie* (1917); M. M. Vukićević, *Kralj Petar od rodjenja do smrti* (1922). (K. ST. P.)

PETER, two *vladike* or prince-bishops of Montenegro.

PETER I (1747–1830), born at Njegosh, succeeded his uncle Sava

in 1782. He was consecrated bishop at Karlovci on the Danube, then in Hungarian territory, in 1784 and then visited Russia. He returned to face a crisis: the pasha of Scutari had invaded the country. Peter somehow united the Montenegrin clans, and the invader was repelled. In 1788 both Russia and Austria requested Peter to join them against the Turks, but the Montenegrins derived no advantage from the war. In the 1790s, however, a Serb migration from Hercegovina filled the gap between Montenegro and its habitual ally, Brda, east of the Zeta River. In 1796 the pasha of Scutari attacked again. Peter led his men in person, and the Turks were routed. The pasha was captured and beheaded (his embalmed head was kept at Cetinje). The union of Brda with Montenegro was formally established, and Peter embodied his peoples' customary laws in a simple code of procedure.

The Treaty of Pressburg (1805) transferred Dalmatia from Austria to Napoleonic France, but, with Russian help, the Montenegrins occupied the town and fjord of Kotor and advanced to Dubrovnik. Russia, however, made peace with Napoleon (1807) and accepted the French annexation of the Dalmatian coast. French rule lasted till 1813; and then, with British naval support, Peter's men again occupied the whole fjord of Kotor. On Oct. 29 delegates from the fjord solemnly accepted the rule of the *vladika;* for a year Kotor was the capital of Montenegro. Then the great powers ordered the restoration of the fjord to Austria and Peter had to return to Cetinje (February 1815).

Peter devoted his last years to attempts to end the vendettas which disrupted his people's life. He had little success, except in uniting the clans to repel the Turks (1819 and 1821) and in enhancing his reputation as "the great and good *vladika.*" He died at Cetinje on Oct. 30 (new style; 18, old style), 1830.

PETER II (1813–1851), Peter I's nephew, was born at Njegosh on Nov. 13 (N.S.; 1, O.S.), 1813, receiving the Christian name of Rado. Succeeding his uncle in 1830, he was consecrated in 1833 as Peter II. He is renowned as a ruler, as a warrior, and, especially, as a poet. His three principal poetical works are "The Ray of the Microcosm," "The False Tsar Stephen the Small," and "The Mountain Garland." Peter II was strong enough to transfer much of the power of the local chieftains to a senate of 12 leading chiefs meeting at Cetinje under his eye. Still more important was his abolition of the office of civil governor, long hereditary in the Radonich family and an obstacle to unity. He had a yearly subsidy from the Russian emperor Nicholas I and used it to start schools and to set up a printing press at Cetinje. His rule was marked by the usual epic conflicts with the Turks, and he even had some success in limiting the inter-clan feuds of his people. He died at Cetinje on Oct. 31 (N.S.; 19, O.S.), 1851, and was buried on the summit of Mount Lovcen (Lovchen). (R. G. D. L.)

PETER OF BLOIS (*c.* 1135–*c.* 1212), author and poet, whose collection of his own letters made him famous throughout the Middle Ages, was born at Blois, the son of noble Breton parents. After studying law at Bologna and theology at Paris, he went in 1167 to Sicily, where he became tutor to the young king William II and keeper of the royal seal. His position aroused much envy and he returned to France about 1169, entering the service of Reginald, archdeacon of Salisbury, and, later, of Rotrou, archbishop of Rouen. He went to England in about 1174 and served in the household of successive archbishops of Canterbury. From about 1179 to 1183 he was chancellor of Archbishop Richard. He became archdeacon of Bath in 1182, and exchanged this for the archdeaconry of London in 1201–02. He was also canon of several churches and for a time dean of Wolverhampton. He died in 1211 or 1212.

Peter of Blois was a prolific writer, but his only work that obtained a wide circulation was his collection of letters. These were written partly in his own name and partly in the names of kings and queens, archbishops, bishops, and even popes. Among the last, the most important was the *Instructio fidei catholicae* which Pope Alexander III sent to the Seljuk sultan of Iconium, probably in 1179. There is no reason to doubt that these letters, often regarded as mere literary exercises, are substantially genuine. The first collection of about 100 letters was made late in Henry II's reign (1154–89) and its success soon encouraged the author to make considerable additions. Thereafter it attracted many apocryphal pieces.

Peter had been an excellent poet of the new school of erotic writers. But he later became ashamed of this, and only a few of his poems, mostly of a moral and satirical character, have been certainly identified. His other works include a collection of sermons, a treatise on friendship (*De amicitia Christiana*) largely pillaged from Aelred of Rievaulx, an unprinted treatise on letter writing, a lively dialogue between Henry II and the abbot of Bonneval, an anti-Jewish tract, and a series of writings designed as an incentive to the Third Crusade. The chief virtues displayed in these works are great versatility, literary skill, and a command of classical and biblical learning. The chief defects are shallowness of thought and barefaced plagiarism. Nevertheless, Peter was a serious and vivid writer and one of the best examples of the learned men of affairs who flourished in England in the late 12th century. His works were edited by P. Goussainville (1667) and reprinted in J. P. Migne, *Patrologia Latina,* vol. ccvii (1855). Of the poems there printed only no. i, ii, v, and vi are genuine, and of these no. ii should be divided into five separate poems. Other poems of Peter's are no. 29–31 in *Carmina Burana,* edited by A. Hilka and O. Schumann, vol. i (1930), and no. cviii in *Carmina medii aevi,* edited by H. Hagen (1877).

PETER OF COURTENAY (d. 1219?), Latin emperor of Constantinople, was a son of Peter of Courtenay (d. 1183) and a grandson of the French king, Louis VI. Having, by a first marriage, obtained the counties of Auxerre and Tonnerre, he took for his second wife Yolande (d. 1219), who brought him the marquisate of Nevers. She was a sister of Baldwin I and Henry of Flanders, the first and second Latin emperors of Constantinople. When Henry of Flanders died without sons in 1216, Peter was chosen as his successor. Consecrated emperor at Rome, in San Lorenzo outside the walls, by Pope Honorius III on April 9, 1217, he embarked at Brindisi with an army and a papal legate on ships supplied by the Venetians, for whom he undertook to conquer Durazzo (Durres) from the Greek despot of Epirus, Theodore Angelus. Having failed in this enterprise, he set out along the overland route toward Thessalonica. But in the mountains near Elbasan he was treacherously seized by Theodore, and died, probably by foul means, after an imprisonment of at least two years.

See J. Longnon, *L'Empire latin de Constantinople* (1949); D. M. Nicol, *The Despotate of Epiros* (1957). (D. M. N.)

PETER I OF DREUX, called MAUCLERC (1190–1250), duke or count of Brittany from 1213 to 1237, was a French prince of the house of Capet, being the second son of Robert II of Dreux and so first cousin once removed to King Philip II Augustus, at whose court he was brought up. At first destined for the church, he was married in 1213 to Alix, daughter of the heiress Constance of Brittany by her third husband, Guy of Thouars. Philip II Augustus, who had assumed the *bail* or custody of Brittany on the murder of Alix's half brother Arthur I (*q.v.*), received Peter's homage for Brittany and transferred the *bail* to him. After Alix's death (1221), Peter retained control of Brittany as guardian of his son John I (born 1216 or 1217). Peter was styled duke by himself and by the Bretons, count by the French.

Peter energetically asserted his authority over the Breton lands. Henry of Penthièvre, a minor, who had been proposed for marriage to Alix, was forced to surrender most of his fiefs into ducal custody (1214); Conan of Léon, Henry's original guardian, was dispossessed of his chief seat (1216); and in the Battle of Châteaubriant (1223) Amaury of Craon was defeated in his attempt to take Ploërmel, which Peter held to have escheated to the ducal domain. The Frenchman Raoul, bishop of Quimper, helped to

introduce the usages of the Capetian chancery into Brittany; and Peter sought the support of the towns, granting a number of charters of privileges.

Peter was called Mauclerc ("bad clerk") either because his training for the church was abortive or because he quarreled with the episcopate. A dispute with the bishop of Nantes (Étienne de La Bruière) over Peter's imposition of a monopoly on wood, salt, and flour culminated in the excommunication of Peter and in an interdict (1219) before the duke submitted (1221). Later the duke's building of fortifications on episcopal lands led to a dispute with the bishop of Rennes (Josselin de Montauban): excommunicated again, Peter at the Assembly of Redon (1227) engaged the secular lords to refuse payment of tithes and other dues to the church and to ignore its sentences; only in 1230 was he absolved.

Having gone to England twice during the expedition of Prince Louis (1216–17; *see* LOUIS VIII), Peter went again in 1218 and obtained seizin of the earldom of Richmond in 1219. He cooperated with the French, however, against the English king's men in Poitou (1224). He also helped Louis VIII's campaign in Languedoc (1226). But on Louis VIII's death Peter joined the movement against Blanche of Castile, regent for Louis IX. His first revolt won him generous concessions (Treaty of Vendôme, March 1227); but in October 1229 he renounced his allegiance to France and did homage for Brittany to Henry III of England. There followed an English expedition to Brittany (1230); a French attack and a three-year truce (1231); and a final French attack (1234), after which Peter submitted to Louis IX. A humiliating inquest into his conduct of affairs was held at St. Brieuc in 1235.

When his son John came of age (1237), Peter had to renounce Brittany. Thenceforward he was merely count of Braine. After a first crusade (1239–40), he went again in 1248 to Egypt, fell sick, and died at sea on his way home in 1250.

PETER DES RIVAUX (*c.* 1190–1262), Poitevin administrator under Henry III of England, the son (but not necessarily bastard) or nephew of Peter des Roches, bishop of Winchester, was born in Poitou and reached England before 1204. He became a king's clerk (1218) but was dismissed (1223) and subsequently exiled when Peter des Roches lost power. Returning to England under Henry III's protection (1230), in June 1232 he was made treasurer of the household, keeper of the wardrobe and of the privy seal as the first step in ruining the justiciar Hubert de Burgh. The latter's fall (July–November 1232) enabled Peter to begin the reorganization of royal finance and administration which Henry III and Peter des Roches intended. The entire royal administration was concentrated in Peter's hands as treasurer of the household: justiciarship, chancery, and exchequer were all completely subordinated to him; he was made treasurer of the exchequer (January 1233), keeper of wardships and escheats, keeper of many great royal castles, chief justice of the forests, sheriff of 21 shires, exercising these offices by deputies chosen by himself. Peter began a drastic and skilful overhaul of the financial and administrative system of exchequer, household, and shires which, if logically completed, would have made Henry III the richest and most absolute king in Europe. But in 1234 the English magnates, led by Archbishop Edmund Rich (St. Edmund), compelled Henry to dismiss Peter des Rivaux. Though his influence was still perceptible in later years, and he became a baron of the exchequer once more in 1253 and keeper of the wardrobe again (1257–58), his plans never matured. Dismissed by the baronial reformers in 1258, he died in England in 1262.

See T. F. Tout, *Chapters in the Administrative History of Medieval England*, vol. i, rev. ed. (1937); F. M. Powicke, *King Henry III and the Lord Edward*, vol. i (1947). (R. F. T.)

PETER DES ROCHES (d. 1238), Poitevin diplomat, soldier, and administrator, one of the ablest statesmen of his time, enjoyed a brilliant but checkered career, largely in England in the service of King John and Henry III. As bishop of Winchester from 1205 to 1238 he organized and added to the financial resources of his see.

He first appears at Richard I's court in the Touraine and Poitou, where he held his earliest ecclesiastical appointments. He went to England with King John, received English benefices, and was promoted in 1205 to the see of Winchester. His election was a result of direct royal influence. He remained in England and retained his see throughout the interdict (1208–13), filling several administrative and military roles, and helping in the negotiations between John and the pope. He became chief justiciar in 1214, but was unpopular and was replaced in June 1215. He supported John loyally during the war with the barons and was one of his executors. Peter crowned Henry III and became his tutor. As the most influential Poitevin in the country, he headed that group of alien officials and soldiers which suffered political defeat at the hands of the justiciar, Hubert de Burgh, in 1223–24. Peter himself lost his position as tutor when Henry declared his majority in 1227. He then accompanied the emperor Frederick II's crusade and reached Jerusalem. In 1230 he helped to reconcile Frederick with the pope and in the next year negotiated a truce between Henry III and the French. On his return to England in 1231 he influenced Henry III to promote his nephew, Peter des Rivaux, to numerous posts, and brought about Hubert de Burgh's fall in 1232. However, the administrative methods he advocated led to baronial opposition in 1233, and in 1234 Henry III dismissed Peter from favour and his nephew from office. Des Roches went abroad again and in 1235 served as a soldier and diplomat with Pope Gregory IX. He returned to England in 1236 and died at his castle at Farnham in June 1238.

See S. Painter, *The Reign of King John* (1949); F. M. Powicke, *King Henry III and the Lord Edward*, 2 vol. (1947). (J. C. Ho.)

PETER OF SAVOY (1203/13–1268), called "the little Charlemagne," counselor of Henry III, king of England, and uncle of Henry's queen, Eleanor of Provence, was born at Susa, the sixth (?) son of Thomas I, count of Savoy, and of Margaret, daughter of William I, count of Geneva. Placed by Thomas in the church, he renounced clerical status (1234/36) on inheriting lands from his father in Bugey and from his mother in Vaud, married his cousin Agnes (d. 1268), heiress of Faucigny, and won fame in war, diplomacy, and administration, vigorously expanding his dominions in Vaud and Valais. In 1240 Henry III invited him to England, gave him the honours of Richmond (without the title of earl) and of L'Aigle, and made him a valued counselor and ambassador. Though Peter still spent much time in Savoy, Henry used Peter's knowledge and prestige and his influence as one of the strategically placed and powerful family of Savoy to promote his own ambitions in Italy and at the papal and imperial courts. Peter acted independently in England, winning the trust of the English barons, especially of Simon de Montfort, advising Henry honestly, and openly supporting the reforms of 1258, when he joined the reforming council of 15. Alienated by Montfort's extreme radicalism early in 1260, Peter thereafter supported Henry loyally. Unexpectedly inheriting the county of Savoy (June 1263), Peter left England to dislodge a rival claimant, his nephew Thomas of Acaja, and never returned, though he helped Henry from afar. He resigned the honour of Richmond before May 6, 1266, and died at Pierre-Châtel about May 15, 1268, having greatly strengthened the influence of Savoy.

Wurstemberger, *Peter der Zweite, Graf von Savoyen*, 4 vol. (1856–58); C. W. Previté-Orton, *The Early History of the House of Savoy (1000–1233)* (1912). (R. F. T.)

PETER THE HERMIT (d. 1115), the Picard preacher whom later writers credited with the role in fact played by Pope Urban II in the launching of the First Crusade. He was born in the diocese, most probably in the town, of Amiens. Dedicated to religion, he is said to have attempted a pilgrimage to Jerusalem about 1093. When Urban proclaimed the crusade at Clermont in November 1095 (*see* CRUSADES), Peter began his preaching, traveling from Berry across Champagne and down the Meuse Valley to Cologne, where he arrived in April 1096. His eloquence attracted

thousands of peasants, who may however have taken the cross the more readily in order to escape from the famine then prevalent in their homelands. Leaving Cologne in May, Peter led his exclusively popular following across Europe to Constantinople, which he reached at the end of July. There he joined forces with the similar contingent led by Walter the Penniless, who had insisted on leaving Cologne in advance of him. On Aug. 5–6 the pilgrims crossed the Straits and advanced to Nicomedia (Izmit).

Unable to maintain discipline, Peter soon went back to Constantinople; in his absence the pilgrim hosts under Walter were annihilated by the Turks at Civitot (probably the modern Hersek) on Oct. 21, 1096. Peter waited in Constantinople till the princely expeditions from Western Europe were assembled there (May 1097), and accompanied their march across Anatolia. He was discouraged by the hardships attending the crusaders' siege of Antioch and was dissuaded only with difficulty from abandoning the enterprise (January 1098). When the crusaders were in turn besieged in Antioch, he was sent to challenge Kerbogha to single combat with one of the princes (June 1098). He was appointed almoner of the Christian Army in spring 1099, preached a sermon on the Mount of Olives a week before the storming of Jerusalem in July, and conducted processions in Jerusalem in August. He returned to Europe in 1100. Prior of Neufmoustier, at Huy in the diocese of Liège, Peter died there on July 8, 1115.

See H. Hagenmeyer, *Peter der Eremite* (1879).

PETER (PETERS), **HUGH** (1598–1660), English Independent minister, army preacher, and propagandist during the Civil War and Commonwealth, was born at Fowey, Cornwall. Educated at Trinity College, Cambridge, he was ordained priest in the Anglican Church in 1623. He went to London in 1626 and was appointed preacher at St. Sepulchre's, but his unorthodox views led to the suspension of his preaching licence in 1627. He was in Holland from 1629 to 1635 when he returned to England and sailed to Massachusetts where he succeeded Roger Williams as preacher at Salem in December 1636. He played a leading part in the colony's affairs and helped in the founding of Connecticut. Peter returned to England in 1641 as an agent for Massachusetts but after the Irish Insurrection (October 1641) he went to Ireland as chaplain to a company of adventurers under Alexander, Lord Forbes, which fought against the Irish rebels (June–September 1642). As chaplain to the New Model Army, Peter preached during the campaigns of 1645 and 1646.

He accompanied Oliver Cromwell to Ireland in 1649 and was present at the fall of Wexford. Appointed chaplain to the council of state (1650), he preached at Whitehall continually during the Commonwealth and Protectorate, but his protests against the Dutch War (1652–54) brought him a reprimand from Parliament. During the later years of the Protectorate, his part in civil and military affairs was less prominent. At the Restoration in 1660 he was specially exempted from the Act of Indemnity and at his trial in October 1660 was found guilty of abetting the execution of Charles I. He was executed at Charing Cross, London, on Oct. 16, 1660.

Peter's works included sermons, accounts of battles and sieges, and tracts on legal, economic, and social reforms.

See R. P. Stearns, *The Strenuous Puritan* (1954).

PETER, EPISTLES OF SAINT, two of the seven Catholic (*i.e.*, general) Epistles of the New Testament, ascribed to the apostle Peter. Since his authorship is questioned for the first epistle and rejected for the second, these epistles call for separate treatment.

I PETER

Contents and Theme.—In 5:12 this letter is called one of exhortation and declaration about the true grace of God, in which the readers must take a firm stand. This gives a good division of the main parts, which are as follows:

1:1–2	introduction
1:3–2:10	an exposition of the benefits of the Christian faith
2:11–5:11	admonitions about the right Christian life
5:12–14	concluding greetings

The readers are born anew to a living hope by the resurrection of Jesus Christ and may expect a glorious future in spite of the trials under which they suffer at the present moment, at the revelation of their Lord. Therefore they must live a holy life in accordance with God's calling, knowing for what a high price they have been ransomed—the blood of Christ. They have been born anew by the imperishable Word of God; they form a spiritual temple built on the living stone of Christ and are a royal priesthood, God's own people. As such they have to live among the gentiles. In accordance with an ethical code which is also found in other New Testament Epistles but here has a stamp of its own, the writer then exhorts his readers to subjection to the authorities, in particular slaves to their masters (recalling the sufferings of their Lord as an example) and wives to their husbands. All must live in love and holiness and not fear suffering, even unjust suffering, for Christ died for sinners and entered into his glory. They must break with the pagan way of life and glorify God through their service. Christians should suffer for Christ's sake and not for misdeeds. The elders must take good care of the people, and the younger members must be submissive.

One of the most attractive sides of this letter is the close relationship it expresses between Christian doctrine and practical life. It breathes a spirit of sure hope which is in striking contrast to the suffering and slander experienced by its recipients. But these trials are a test for the genuineness of their faith. The writer lives in expectation of the approaching end of the world and the revelation of Jesus Christ in glory (4:7; 1:5). The letter is clearly addressed to new converts, but the theory that it is a "baptismal sermon" conflicts with its character as a letter.

Authorship and Date.—Authorship and date depend upon decisions about the character of the letter. It is addressed to "the exiles of the dispersion in Pontus, Galatia, Cappadocia, Asia and Bithynia" (1:1). The term dispersion is generally explained in a symbolic sense, used of the Christians who live in exile while their true homeland is in heaven, but both the Old Testament and patristic usage make this widespread interpretation impossible. Except for one highly doubtful text (James 1:1), it is always unequivocally used for the Jewish Diaspora (*q.v.*). From 1:18; 2:9 and especially 4:3–4, it is clear, however, that the letter is addressed not to former Jews but to former pagans. These were the so-called "Godfearers," visitors of the synagogues who had not become proselytes and therefore could not be considered as members of the elect people of God, Israel. Now such persons are assured (2:9) that they do belong to the people of God and that the high epithets of the chosen people are theirs, because the sacrifice, which according to Jewish ritual must be made before a person can become a proselyte, had been offered up in the death of Jesus Christ (1:18–19; 3:18). Throughout the epistle there are numerous parallels with the terminology used in Jewish literature for the proselytes.

The letter has certain parallels with the epistles of Paul, particularly with Rom. 13:1 ff. and Ephesians-Colossians. This does not mean that the writer was dependent upon Paul, for the parallelism exists mainly in passages that have a catechetical structure. A special point in the teaching of this epistle is the preaching to the spirits in prison (3:19–22), which formed the scriptural basis for the church's doctrine of Christ's descent into hell.

The question of authorship depends partly on the dating, which is uncertain. Internal evidence gives no clear indication, and external evidence is lacking. Some scholars try to identify the sufferings expected in 1:6 and taking place in 4:12 with a known persecution of Christians, such as that under Nero in 64, Domitian in 96 or Trajan in *c.* 110. But there is no indication in the epistle that these sufferings were official persecutions organized by the state (on the contrary, the Christians' relationship to the authorities appears friendly in 2:12), and a further objection to Nero's persecution, the only one which took place in Peter's lifetime, is that the suffering is said to be worldwide (*cf.* 5:9), whereas Nero's was confined to Rome. All the passages about suffering can be best understood as referring not to persecution but to the slander to which Christians are exposed (*e.g.*, 3:13 ff.) because they are a minority with social and religious customs differing from those of the people around them.

If the "ransom" in 1:18 refers to the proselyte offering, then the epistle must date from before the destruction of the Temple in the year 70. According to 5:13 it was written in Babylon, which may be an apocalyptic name for Rome (*cf.* Rev. 14:8; 16: 19). The reference to Mark (in 5:13), whose presence in Rome is attested (*e.g.*, Col. 4:10), seems to support this interpretation, but the letter as a whole is not apocalyptic and the sequence of countries mentioned in 1:1 going from east to west in Asia Minor seems to indicate a starting point in the east, so that the eastern city of Babylon with its large Jewish colony among whom Peter might have been a missionary (*cf.* Gal. 2:7–9) could be the source of the letter.

The chief argument against Peter's authorship apart from the possible late date of the letter is that it is written in such good Greek and shows such precise knowledge of the Septuagint that it could not have been composed by an uneducated fisherman. But the author of the letter refers to his assistant Silvanus (5:12), who may have been a more learned man and perhaps was responsible for editing the work of Peter. In 5:1 the author refers to himself as "a witness of the sufferings of Christ," thus implying that he was a disciple of Jesus. It can therefore be concluded that Peter was the guiding spirit of the letter, which should perhaps be dated *c.* A.D. 60. It was used by Polycarp and Papias in the beginning of the 2nd century, was considered as authoritative by Irenaeus, Tertullian, and Clement of Alexandria at the end of the 2nd century, and since then has been an undisputed part of the canon. Doubts about its authenticity first arose in the early part of the 19th century.

II PETER

Contents and Theme.—This epistle has been called "the testament of Peter" because it gives the author's last commandments before his approaching death (1:12–15). He reminds his readers, who are not identified with any particular place, of the great grace they have received and admonishes them to escape from the corruption in the world and to live a virtuous life. Chapter 2 is a long warning against false teachers. Instead of the true Christian teaching, which follows not myths but the sure prophetic word, these heretics lead the churches astray in their licentious, ungodly life. But their destruction is certain as may be seen from various examples of false prophets in the Old Testament. They try to enslave the Christians who have escaped the defilements of the world through the knowledge of Jesus Christ. The readers should remember the words of the holy prophets and the commandment of their Lord according to which scoffers will arise in the last day and deny the return of Jesus in glory and judgment. This promised day will come, but the Lord has delayed it so far because the measure of his time is different from that of men and he wants to give time for repentance. The writer reaffirms the Christian hope for a new heaven and a new earth and exhorts his readers to be faithful and blameless.

Relationship to Jude's Epistle.—This epistle has such a close relationship to that of Jude (*see* JUDE, EPISTLE OF SAINT) that one must have borrowed from the other. Comparison of the parallel passages (1:5 and Jude 3; 2:1 and Jude 4; 3:4 ff. and Jude 5 ff.; 2:10 ff. and Jude 7; 3:2 and Jude 17; 3:14 and Jude 24) shows that II Peter has used Jude and not vice versa. The order of the Old Testament examples in Jude has been remodeled to follow the historical sequence of books. The references to noncanonical books in Jude are left out (the quotation of I Enoch in Jude 14–15 is made unintelligible in II Peter 2:11 because the concrete example of Jude 9 is missing). II Peter also shows a later development in the fact that these false teachers specially deny the second coming and final judgment which is not yet the case in Jude.

Authorship and Date.—This dependence upon Jude makes it impossible to consider the apostle Peter as the author, although the letter purports to be written by "Simon Peter, a servant and apostle of Jesus Christ" (1:1), who states that he was an eyewitness of Jesus' transfiguration (1:16–18), refers to a previous letter (3:1, which is most likely to be I Peter), and speaks about Paul as a contemporary (3:15). The case against Peter is strengthened by other observations: (1) The language is thoroughly Hellenistic, quite different from and more refined than that of I Peter. (2) The writer uses all sorts of typically Hellenistic ideas, such as "virtue" (or "excellence") of God (1:3), virtue connected with faith (1:5), "knowledge" (*gnosis* and *epignosis*) in a specific sense (1:2, 3, 6, 8; 2:20; 3:18), "partakers of the divine nature" (1:4), epopts ("eyewitnesses"), an expression of the mystery-religions (1:16). (3) In his insistence on the second coming of Christ, which began to be denied at the end of the 1st and the beginning of the 2nd century, the author seems to have in mind various Gnostic teachers (*cf.* "cleverly devised myths," 1:16), though it is not possible to identify them in any of the Gnostic groups.

In 3:16 the author seems to know a collection of Pauline epistles. This points to the beginning of the 2nd century, at which time various other books were connected with the name of Peter; *e.g.*, a "Preaching" and a "Gospel." This epistle is not quoted by any author in the 2nd century, however, and Origen, who first mentions it, calls it disputed. Though Hippolytus in the 3rd century uses the letter, Eusebius says it is "contradicted" and Jerome attests that it "is rejected by the majority." But in the course of the 4th century it was gradually accepted (*e.g.*, by Athanasius and Augustine). The Syriac translation, the Peshitta, does not contain it and the Syrian church has not accepted it.

Since the 16th century there have been doubts about its authenticity. Calvin, for instance, held that a disciple of Peter was the author. Although Roman Catholic and a number of conservative Protestant scholars have long defended the authorship of Peter, it is now generally held to be spurious on the grounds set forth in this article. The value of the letter is seen in its defense, against Gnostic spiritualization, of early Christian belief in the truth of the return and judgment of Jesus Christ. The expression "become partakers of the divine nature" (1:4) has since the 4th century deeply influenced the mystical theology of the Orthodox Church. *See* also BIBLE.

(W. C. v. U.)

PETERBOROUGH, CHARLES MORDAUNT, 3RD EARL OF (*c.* 1658–1735), English soldier and politician who attained prominence for his eccentric and irresponsible behaviour during the War of the Spanish Succession. He began his career in the navy. He succeeded to the peerage as Viscount Mordaunt on the death of his father in 1675 and under James II he became one of the earliest supporters of William of Orange. In 1689, after William's accession to the English throne as William III, he was made a privy councillor, first lord of the Treasury, and earl of Monmouth. He remained on friendly terms with the king until 1693. Four years later he was briefly imprisoned for complicity in Sir John Fenwick's conspiracy to assassinate William III. The death of his uncle, Henry Mordaunt, on June 19, 1697, made him 3rd earl of Peterborough.

He returned to court after the accession of Queen Anne (1702) and was sent to Spain in 1705 to command an expedition in support of Archduke Charles of Austria (later the emperor Charles VI), a claimant to the Spanish crown. Peterborough besieged and took Barcelona that year and early in 1706 entered Valencia. He delayed there while Barcelona was besieged by the French and the city was only saved in April because Sir John Leake, bringing reinforcements by sea, ignored Peterborough's orders and sailed

direct to Barcelona. It seems that by this time Peterborough had lost sympathy for the archduke's cause and was instead hoping to advance the claims of the duke of Savoy, Victor Amadeus II. Peterborough visited Italy, without leave of absence, later in 1706, and although recalled in February 1707, made a long tour of Europe, arriving in England only in August. An investigation into his conduct in Spain, begun in the House of Lords in 1708, resulted in complete exoneration and a vote of thanks in 1711. Thereafter the government charged him with various diplomatic missions, chiefly to keep a troublesome man out of the country. He was made a knight of the Garter in 1713. His authority vanished after the accession of George I in 1714. His last grand intrigue was in 1717, when he went to Italy to form a league to drive out the Austrians. The mission ended inconclusively when he was arrested at Bologna, allegedly because, disguised as a woman, he had been unable to forgo wearing his Garter insignia under his skirt. He died on board his yacht off Lisbon on Oct. 25, 1735, and was buried at Turvey, Bedfordshire.

Of fierce and turbulent disposition, Peterborough seems to have been incapable of obeying orders. In his diplomatic wanderings he is said to have seen more kings than any man in Europe. His first wife, Carey, died in 1709. Later (possibly in 1722) he secretly married Anastasia Robinson, a famous singer of great beauty. He was a friend of Jonathan Swift and of Alexander Pope.

See W. Stebbing, *Peterborough* (1890); C. R. Ballard, *The Great Earl of Peterborough* (1929). (B. J. R.)

PETERBOROUGH, a city and seat of Peterborough County, Ontario, Can., on both banks of the Otonabee River, 75 mi. (121 km.) NE of Toronto. Pop. (1961) 47,185. In 1821 Adam Scott founded a sawmill and a grist mill at the site, where five falls descend a total of 50 ft. (15 m.), and it became known as Scott's Plains. In 1825 almost 2,000 Irish settlers arrived under an assisted-emigration plan directed by Peter Robinson, and the town and county were renamed in his honour. Peterborough became a commercial and manufacturing centre of the surrounding area and tourist centre of the Kawartha Lakes region. Canalization of the Otonabee as part of the Trent Canal system provided direct communication with Lake Ontario and Georgian Bay by means of the world's highest hydraulic lift lock (1904). Peterborough was incorporated as a city in 1905. Manufactures include electrical machinery, boats and marine equipment, watches and clocks, cereals, and other products. (F. G. R.)

PETERBOROUGH, a city and municipal borough in the county of Huntingdon and Peterborough, Eng., 19 mi. (31 km.) N of Huntingdon by road. Pop. (1961) 62,340. It is the seat of a bishop, and an important industrial and agricultural centre on the western edge of the Fens (*q.v.*) and on the Nene River which is navigable from there to the sea by ships of 500 tons burden. Until 1965 Peterborough was within the separate administrative county of the Soke of Peterborough (*see* below), Northamptonshire.

In the centre of the city is the Cathedral of St. Peter, the third church on the site, begun in 1118 and an important example of a large church in the Late Norman style. It is built mainly of limestone from Barnack, 10 mi. (16 km.) NW of Peterborough. The cathedral was consecrated in 1238. The west front, one of the finest of the Early English period, seems to have suffered from the builders' changes of plan, and the Perpendicular porch (1375) between the central piers, probably to strengthen the front, increases the unharmonious effect. The flanking turrets have Decorated and Perpendicular spires and pinnacles. The northwestern tower was begun in 1265 and the central tower replaced a Norman lantern in the 14th century (rebuilt 1883–86). A noteworthy feature of the interior, which is almost entirely Late Norman, is the painted ceiling (*c.* 1220) of the massive nave, probably the only surviving ceiling of the period in England. The lozenge patterns contain curious figures including a half-human, man-eating creature, a donkey, a Janus head, and kings and queens. The magnificent fan vaulting of the late Perpendicular New Building or retrochoir (*c.* 1500) is probably by John Wastell, who was responsible for the fan vaults in King's College Chapel, Cambridge. The Hedda Stone, a block of black stone with figures of the apostles in relief, is an interesting example of Saxon sculpture dated about 800. There is some fine stained glass by William Morris (1862).

The Outer Gate connects the cathedral precinct with the Market Place. It was built at the end of the 12th century but much altered in the early 14th century. Among much Victorian building the most interesting remains are the Abbot's Gate (early 13th century), with the Knights' Chamber above, St. Thomas's Chapel (*c.* 1330), the chancel of a church whose nave was pulled down and used in the building of the parish church (*see* below), the richly decorated Priory Gate (early 16th century), and the 13th-century infirmary.

Apart from the cathedral Peterborough has few interesting architectural features. The parish Church of St. John the Baptist in the Market Place was completed in 1407 in the Perpendicular style. Close by is the Market Cross (or Old Town Hall), rebuilt or enlarged 1669–72. Buildings of note near Peterborough are Thorpe Hall (1653–56), and St. Botolph's Church (1263) at Longthorpe with a bishop's chair and pointed-trefoil windows. Longthorpe Hall, a fortified house of the early 14th century, contains remarkable wall paintings of the same period.

The first bridge over the Nene at Peterborough was built in 1308. The present bridge dates from 1934. In the early 1930s a major reconstruction scheme was carried out in the centre of the city, and the town hall and municipal buildings were built. The town museum and art gallery is in Priestgate. Educational establishments include the King's School, Deacon's School, and the Girls' County School.

Peada, king of Mercia, founded the Benedictine Abbey of SS. Peter, Paul, and Andrew in the village of Medeshamstede in 655. In 870 it was destroyed by the Danes and rebuilt in the following century by Aethelwold, bishop of Winchester, with King Edgar's help. Later, because of its wealth, it was known as Gildenburgh (golden borough). At the beginning of the 11th century Abbot Elsinius made a great collection of relics, including the arm of St. Oswald. After the Norman Conquest, when William I, the Conqueror, had installed a Norman abbot, the monastery was sacked by Hereward the Wake and the Danes. The monastery and most of the town were destroyed in a fire in 1117. The town became a borough in the 12th century and a city in 1541 after the monastery had been dissolved, and the monastery church became a cathedral. The interior was badly damaged by Cromwell's troops in 1643. Catherine of Aragon is buried there and the cathedral contained the original tomb of Mary Stuart, queen of Scots.

Weaving and wool combing were important in the 14th century. With the reclamation of the Fens, Peterborough grew as a market centre, and when the town became an important railway junction in the mid-19th century industries were established. Principal engineering products are diesel engines, bakery and laundry plant, steam turbines, pumps, electric appliances, and mechanical handling equipment. Fruit and vegetables are canned, and sugar beet processed. There are large brickworks at Fletton to the south. Apart from weekly markets an agricultural show is held in July and the Bridge Fair early in October. Peterborough is in the Peterborough parliamentary division of Northampton.

The Soke of Peterborough was a separate administrative county from 1884 to 1965, but it was included in Northamptonshire for purposes of the lord lieutenancy. It stretched from Market Deeping (Lincolnshire) in the north to Peterborough in the south and comprised the rural districts of Barnack and Peterborough as well as the city of Peterborough. The part of the Soke north of the Nene is the Liberty of Peterborough, originally the area under the jurisdiction of the abbot of the monastery. Fens and marshes are in the south of the area and higher land in the north, where there are some fine Saxon churches. In the northwestern corner is the great Elizabethan mansion of Burghley House, home of the marquess of Exeter.

See N. Pevsner, *Northamptonshire* (1961).

PETER CHRYSOLOGUS, SAINT (*c.* 400/406–*c.* 450), Latin father and doctor of the church. Little is known with certainty of his life. He was born at Imola in northern Italy and

about 433 became bishop of Ravenna, the residence of the western Roman emperor. Peter was a zealous pastor, who preached regularly to his flock and, with the aid of the empress regent Galla Placidia, promoted the construction of church buildings. He was a close friend of Pope Leo the Great and was revered in both the east and the west for his eloquence and orthodoxy. In 448 Eutyches, the Monophysite heresiarch, appealed his condemnation to Peter as well as to Pope Leo. Peter's kindly reply withheld judgment but counseled obedience to the bishop of Rome. Soon afterward he retired to Imola and there died about 450. Many of his homilies survive, together with the letter to Eutyches. In the standard collection of 176 sermons, however, made in the 8th century, several are unauthentic, while other genuine homilies probably exist among the works of other authors. His sermons are short and popular, stressing the fundamental Christian doctrines and the duties of Christian life. They are not profound, original or elegant, but they reflect the needs and ideals, the virtues and vices of the times. The appellation *Chrysologus* ("Golden Orator") arose later, probably to create a western counterpart to the east's John Chrysostom. He was given the title of doctor of the church in 1729. His feast day is Dec. 4.

See G. Ganns, *Saint Peter Chrysologus: Selected Sermons* (1953).
(Jn. Sr.)

PETER CLAVER, SAINT (Pedro Claver) (1581–1654), missionary to the Negro slaves in Spanish America, was born at Verdu, Catalonia, in 1581 and entered the Society of Jesus in 1602. While studying at the college of Palma in Majorca he was inspired by the holy lay brother St. Alphonsus Rodriguez to volunteer for the missions of New Spain. In 1612 he was sent to Cartagena (in modern Colombia), where he was ordained in 1616. At Cartagena, the chief slave market of the new world, every month slave ships disembarked 1,000 or more Negro slaves. The condition of these poor wretches aboard ship and in the slave pens was horrible beyond description, and the new priest, declaring himself "the slave of the Negroes forever," dedicated his life to them. Accompanied by interpreters and carrying food and medicines, he boarded every incoming slave ship and constantly visited the slave pens, befriending and defending the oppressed, nursing the sick and dressing their sores, teaching religion and baptizing them. His heroic labours met with strong opposition, and even ecclesiastics lent their ears to charges of indiscreet zeal. Claver persevered for 38 years, baptizing, according to reliable estimates, 300,000 slaves.

He died at Cartagena Sept. 4, 1654. Pope Leo XIII canonized him on Jan. 15, 1888, and on July 7, 1896, declared him the patron of all Catholic missions to Negroes. His feast day is Sept. 9.

PETERHEAD, a small and parliamentary burgh and seaport in the Buchan district of Aberdeen County, is the most easterly town in Scotland and lies 32 mi. (51 km.) NNE of Aberdeen city by road. Pop. (1961) 12,502. The town, built of locally quarried red granite, was founded in 1593 by George Keith, 5th earl marischal. A statue to James Keith, who was born in 1696 at Inverugie Castle (2 mi. [3 km.] NW) and became a Prussian field marshal, was presented to the burgh in 1868 by William I of Prussia and stands in front of the Town House (1788). The Old Pretender (James, prince of Wales) landed at Peterhead on Christmas Day, 1715, and, for helping him in this exploit, both the field marshal and his brother, George Keith, 10th and last earl marischal, were exiled. The estate of Peterhead was bought in 1720 by an English building company, but the company failed and the lands were acquired by the Merchant Maiden Hospital of Edinburgh, which is now administered by the Merchant Company Education Board, Edinburgh.

There is some local trade from the port which is a station of the herring fisheries and head of a fishery district, with a large herring fleet. The north and south harbours lie between the town and Keith-Inch, an island suburb, and the isthmus dividing them is pierced by a canal. In the north harbour there are a graving dock and a patent slipway. The breakwaters, enclosing about 400 ac. (162 ha.) of water (the Harbour of Refuge), were built between 1886 and 1958, principally by convict labour from the prison near Salthouse Head. The leading industries are fish curing, fish and vegetable canning, woolen manufacturing, and light engineering. There is a growing export trade in oats, potatoes and other crops, and beef from the surrounding countryside.
(A. Cg.)

PETERLOO, or the Manchester massacre, a name given in English history to a meeting held on Aug. 16, 1819, in St. Peter's Fields, Manchester. It followed a number of other large political meetings in a year of industrial depression, particularly among the handloom weavers who were new converts to radicalism. The price of food was exceptionally high, and the August meeting was intended to be a great demonstration of the discontented. Its political object was to demand the reform of Parliament, and it was attended by about 60,000 persons, including an unusually large proportion of women and children. Though none was armed and their behaviour was admittedly wholly peaceable, the magistrates, who had been nervous before the event and were alarmed by the mood and size of the crowd, ordered the Manchester yeomanry to seize the speakers immediately after the meeting had begun. The yeomanry, who were untrained Manchester "loyalists," bitter opponents of the radicals, did not confine themselves to arresting the leaders, but made a general attack upon the audience, crying "Have at their flags," and cutting them down with the edge as well as the flat of their sabres. The chairman of the bench of magistrates thereupon ordered the 15th hussars and the Cheshire yeomanry also to charge the crowd, and in ten minutes the place was cleared except for bodies. The numbers of killed and wounded were disputed; probably about 500 people were injured and 11 were killed. The news of Peterloo shocked opponents of the government throughout the country, but the government did not repudiate the magistrates.

Bibliography.—*Memoirs of H. Hunt, Esq.* (1820–22); S. Bamford, *Passages in the Life of a Radical* (1893); F. A. Bruton, *Story of Peterloo* (1919), *Three Accounts of Peterloo* (1921); D. Read, *Peterloo: the "Massacre" and its Background* (1958). (A. Bri.)

PETER MARTYR, a name commonly used in English for (1) St. Peter Martyr (d. 1252), killed by Cathari; (2) Pietro Martire d'Anghiera (1457–1526), Italian historian; and (3) Pietro Martire Vermigli (*q.v.*).

PETER NOLASCO, SAINT (Pierre Nolasque) (*c.* 1189–1256), founder of the order of Our Lady of Ransom (de Mercede), commonly called Mercedarians or Nolascans, was born of noble parents at Mas-Saintes-Puelles in Languedoc. The facts of his life are obscure and controversial. Declining to marry, he dedicated himself to God's service among the poor and abandoned. The belief that he took part in the Albigensian campaign or was tutor to James I, king of Aragon, has been doubted. He went to Spain, where the Moors held many Christians in slavery. Peter spent his patrimony ransoming them and got others to contribute. Later he determined to found a religious institute whose primary object would be the ransoming of Christian slaves. The extent of Raymond of Peñafort's (*q.v.*) influence on the founding of the order has been disputed by the Dominicans and Mercedarians, and consequently the date of ceremonial foundation in Barcelona is variously given as 1218, 1223, 1228 and 1234. The *documento de los sellos*, a notarial act, treating of Our Lady's simultaneous apparitions, commanding the founding of the order, to Peter himself, Raymond and James I, has been proved a forgery. Peter twice went to Africa to redeem slaves. He resigned his offices of master general and ransomer some years before his death at Barcelona on Dec. 24/25, 1256. He was canonized in 1628, and his feast day is Jan. 28. *See* also Mercedarians.

PETERS, KARL (1856–1918), German explorer, one of the founders of German East Africa, was born at Neuhaus on the Elbe on Sept. 27, 1856. He visited London to study English principles of colonization and on returning to Berlin founded the Society for German Colonization in 1884. The same year he went to the coast of east Africa where he made treaties in favour of Germany with native chiefs. A further expedition led by Peters under the auspices of the German East Africa company in 1887, avowedly for the relief of Emin Pasha, extended the sphere of German influence. Peters reached Uganda early in 1890 and concluded a treaty with the king, but without the support of the German government. This treaty was declared void as an agreement had been reached between Germany and Great Britain by which Uganda was left in the British sphere. Back in Germany Peters published in 1891 an account of his expedition, *Die deutsche Emin Pasha Expedition* (*New Light on Dark Africa*). He was imperial high commissioner for Kilimanjaro in 1891, but in 1897 was deprived of his commission for misuse of official power in his treatment of the natives; he was reinstated in 1906. From 1899 to 1901 he explored the Fura district and Macombe's country on the Zambezi, with a view to commercial exploitation, and described his discovery of ancient cities and deserted gold mines in *Im Goldland des Altertums* (*The Eldorado of the Ancients;* 1902). Peters died at Woltorf, near Brunswick, on Sept. 10, 1918.

See H. T. Schorn, *Dr. Carl Peters* (1920).

PETERSBURG, a city of southern Virginia, U.S., 23 mi. S. of Richmond on the Appomattox river. In 1646 Ft. Henry was built at the falls of the Appomattox, the site of the present city. Maj. Peter Jones became commander of the fort in 1675; from him, directly or indirectly, Petersburg seems to have derived its name. In 1733 Col. William Byrd II surveyed the site but it was not until 1748 that an act of the colonial legislature established the town of Petersburg. In 1784 Petersburg, Blandford, Pocahontas and Ravenscroft were combined and incorporated as one town, Petersburg. During the American Revolution it was captured by British troops under William Phillips and Benedict Arnold on April 25, 1781. On May 20 Cornwallis arrived with his army and a few days later began the campaign that was to end with his surrender at Yorktown.

Petersburg was the scene of prolonged and bitter fighting during the American Civil War. In June 1864, following his costly failure to defeat Gen. Robert E. Lee at Cold Harbor, Gen. U. S. Grant moved his army to the south side of the James. The southern approaches to Richmond were blocked by Petersburg and Grant's efforts to take the city developed into a virtual siege that lasted for 10 months. On April 2, 1865, his defenses crumbling and his army in danger of destruction, Lee ordered a withdrawal from Petersburg. Richmond was evacuated on April 3 and the war was all but over. (*See* also PETERSBURG CAMPAIGN.)

Petersburg National Battlefield (formerly Military Park), scene of the "Battle of the Crater," is only one of many historic sites in and around Petersburg. Centre Hill mansion, built in 1823, was an antebellum show place; it now houses an important collection of Civil War relics. Bristol Parish Church in Blandford, built in 1737, has been restored. Adjoining it is the Confederate cemetery.

Petersburg has more than historic importance; it is a progressive city engaged in a long-range, comprehensive program of modernization and improvement. Its industrial output includes cigarettes and other tobacco products, optical lenses and frames, trunks and hand luggage, wearing apparel, and glass fibre boats. Nearby Hopewell has large plants producing industrial chemicals, paper and allied products, and man-made fibres. Petersburg has a council-manager form of government, in effect from 1920.

Virginia State College and Central State Hospital lie just outside Petersburg. Ft. Lee, the U.S. army quartermaster training command, is one-half mile east of the city. For comparative population figures *see* table in VIRGINIA: *Population.* (M. BR.)

PETERSBURG CAMPAIGN, a series of military operations in southern Virginia, 1864–65, during the final months of the American Civil War. Petersburg, an important rail centre 20 mi. S of Richmond, was a strategic point for the defense of the Confederate capital. When the 1864 campaign opened there were only two railroads still linking Virginia with the rest of the Confederacy: the Petersburg and Weldon, running due south from Petersburg, and the Richmond and Danville, extending southwest from Richmond. The Southside Railroad, connecting Petersburg with Lynchburg, intersected the Richmond and Danville at Burkeville. The severance of these lines was a major Union objective during the last year of the war.

On May 5, at the very outset of the 1864 campaign, Petersburg was endangered by the landing of Gen. Benjamin F. Butler's Army of the James at Bermuda Hundred and City Point, in close proximity to both Richmond and Petersburg. Butler, an incompetent political general, was driven back at Drewry's Bluff on May 16 by a smaller force under Gen. *Pierre G. T. de Beauregard.* (For the convenience of the reader the names of Confederates are printed in italics.) At the conclusion of the engagement the Federals found themselves confined by Confederate fortifications to the eastern end of Bermuda Hundred peninsula.

The next serious threat to the railroads did not come until mid-June. At that time Gen. *Robert E. Lee's* army, following the Wilderness–Cold Harbor operations, had been reduced by casualties and detachments to 37,000 men. There were about 7,000 troops in the Richmond garrison, while *Beauregard's* force did not exceed 8,000; the grand total was only 52,000. In contrast Gen. U. S. Grant had about 110,000 officers and men organized into one cavalry corps and six infantry corps, two of the latter belonging to Butler's Army of the James. After his bloody repulse at Cold Harbor, Grant decided to carry out a sweeping flank movement against *Lee's* communications by marching southeastward, bridging the James River, and then turning westward against Petersburg. Should Petersburg fall, *Lee* would either have to attack Grant with vastly inferior numbers or else abandon Richmond and retreat hurriedly to protect his communications. Given careful planning, the movement across the James involved few risks. By beginning the disengagement on the night of June 12 Grant was able (as he had been throughout the campaign) to steal a day's march on *Lee.* Furthermore, in heavily wooded country traversed by few roads, it was relatively easy for Grant to conceal the movement of his army from the enemy, whom he outnumbered more than two to one. Gen. William F. Smith's corps, brought from Bermuda Hundred for the Cold Harbor operation, embarked at White House to rejoin Butler. The rest of the army marched overland to Wilcox's Landing, where a pontoon bridge was built on June 14.

Lee, discovering Grant's absence on the morning of the 13th, shifted his army to the Frayser's Farm–Malvern Hill sector; there he was confronted by Union cavalry and Gen. Gouverneur K. Warren's corps, which were screening the Federal march to the James. Warren soon withdrew, but *Lee's* outnumbered troopers were unable to penetrate the opposing cavalry and locate Grant's army. *Lee* had to consider two major possibilities: Grant might, in a repetition of his former movements, make a short flank march followed by a frontal attack; or he might cross the James and attack Petersburg. *Lee* could not uncover Richmond until he received definite information that the enemy had crossed the James. Under the circumstances *Lee* had to rely almost exclusively on *Beauregard,* commanding at Petersburg, for estimates of Union strength south of the James. Unfortunately for *Lee,* the reports sent by *Beauregard* were scanty and vague. *Lee's* response was correspondingly hesitant and the result was a golden opportunity for the Federals to take Petersburg.

When Smith's corps reached Bermuda Hundred, it was ordered to cross the Appomattox River and move on Petersburg. Smith arrived before the outer defenses of the town on the morning of the 15th, when it could have been captured easily, but caution engendered by Cold Harbor plus the accidental absence of the corps artillery delayed Smith's main attack until 7 P.M., when the outer line of works was carried. *Beauregard's* men withdrew a short distance and, with the timely assistance of a division from *Lee's* army, established a new line. That night *Beauregard* stripped the Bermuda Hundred fortifications to reinforce Petersburg. Before noon on the 16th there were three Union corps on the field, W. F. Smith, W. S. Hancock, and A. E. Burnside; 53,000

men to *Beauregard's* 10,000. By failing to attack before 5 P.M., however, the Federals did no more than breach the new Confederate line. The attack was resumed on the morning of the 17th and made considerable progress, though at heavy cost; that night *Beauregard* retreated to a previously prepared position. Gen. George G. Meade ordered a general assault for the 18th but continuing confusion in the Union command delayed the advance until afternoon, by which time *Lee* was on the field with a large part of his army and severely repulsed the Federals. Thus Grant's well-executed shift south of the James was climaxed by the bungled attacks on Petersburg, where the Federals had the advantage of great odds during June 15–17. Contributing to the command failures in Grant's army was the growing disinclination on the part of both officers and men to assail entrenchments.

The Siege.—The siege of Richmond and Petersburg may be said to have begun on June 19. Both armies rapidly constructed formidable fortifications that ultimately curved from a point east of Richmond to a point southwest of Petersburg—about 35 mi. By continually extending his left flank Grant attempted to sever *Lee's* rail connections with the Carolinas, precipitating actions at Jerusalem Plank Road (June 22), Reams' Station (June 29 and Aug. 24), Globe Tavern (Aug. 18–19), Boydton Plank Road (Oct. 27), and elsewhere. Union losses were heavy but by late August Grant's fortified lines had crossed the Petersburg-Weldon Railroad and were reaching out ominously in the direction of the Southside Railroad. During this same period Union frontal assaults on the Confederate lines met with mixed success. On July 30 one of the most spectacular events of the war occurred when the Federals exploded a huge mine under a part of *Lee's* works known as Elliott's salient, about 1½ mi. S of the Appomattox. A breach was effected but the follow-up assault was mismanaged, and the Federals were finally driven back after losing 4,000 men. North of the James, Grant's most notable achievement was the capture of Ft. Harrison on Sept. 29.

At the end of the year *Lee* still held Richmond and Petersburg; success on one front, however, could not compensate for the disasters that had befallen Confederate armies elsewhere. The breakdown and destruction of Southern railroads meant that *Lee's* men were ill-fed to the point of physical exhaustion, and the lack of draft animals and cavalry mounts almost immobilized the army. Hunger, exposure, and the apparent hopelessness of further resistance led to increasing desertion, especially among recent conscripts. The major strategic problem facing *Lee* was to stop the advance of Gen. William T. Sherman, who had turned north from Savannah and by mid-March was in central North Carolina. There he was opposed by a small force under Gen. *Joseph E. Johnston*. If Sherman was to be stopped, *Johnston* had to be reinforced, and the only possible source of men was *Lee's* army. Therefore *Lee* decided to assault Grant's line a short distance south of the Appomattox. If successful the attack would force Grant to pull in his left flank, shortening the lines *Lee* had to defend and allowing him to send help to *Johnston*. In the ensuing battle of Ft. Stedman (March 25, 1865) the Confederates were driven back by counterattacks after breaching the Union line, losing about 3,500 men. *Lee* was now left with 50,000 men; Grant's strength at this time was 120,000.

Shortly after Ft. Stedman, Grant made his final stroke against the Southside Railroad by sending a flanking column 50,000 strong around the Confederate right. To meet this column *Lee* sent 10,600 infantry and cavalry—all he could spare—under Gen. *George E. Pickett* and Gen. *Fitzhugh Lee*. This force was crushed at the Battle of Five Forks (April 1). The next day Grant assaulted the thinly manned lines in front of Petersburg, broke them in several places, and drove the defenders back to the inner defenses. *Lee* immediately informed Pres. *Jefferson Davis* that Richmond and Petersburg could no longer be held; the evacuation was carried out that night.

Aftermath.—It was *Lee's* purpose to march southwestward and join *Johnston*. As his first point of reconcentration he chose Amelia Court House, 40 mi. W of Petersburg, where a supply train could meet the army. When Amelia was reached on April 4 it was discovered that, by error, the train had gone on to Richmond. The Confederates were forced to spend April 5 vainly searching the neighbouring countryside for food. This delay, aggravated by the exhaustion and starvation of men and teams, allowed the westward-marching Federals to interpose between *Lee* and *Johnston*. On the 6th the Confederate rear guard was overwhelmed at Sayler's Creek, leaving *Lee* with only 15,000 effective troops. On the 7th the Confederates reached Farmville, where *Lee* expected to find food and then move north of the Appomattox, putting the river between his army and its pursuers. Through failure of subordinates to destroy High Bridge, however, Union troops were able to follow immediately, and *Lee* was forced to resume the retreat before all of his men could be fed. His next objective was Appomattox Station on the Southside Railroad where, again, he hoped to find supplies. On the afternoon of April 8 the army reached Appomattox Court House, only 3 mi. from the railroad; at 9 P.M. *Lee* learned that his adversary had won the race: Union troops blocked further advance to the west. An attempt on the morning of the 9th to cut through to Appomattox Station failed.

The Army of Northern Virginia, with no more than 8,000 effectives, was surrounded by 50,000 Federals, with as many more quickly available. "There is nothing left for me to do," said *Lee* to his staff, "but to go and see General Grant, and I would rather die a thousand deaths." The two commanders met on the afternoon of April 9 in the Wilmer McLean house at Appomattox Court House. According to the humane terms proposed by Grant, Confederate officers and men were paroled and allowed to return to their homes. Other Southern armies surrendered in quick succession and within two months all resistance had ceased. *See* also AMERICAN CIVIL WAR.

(L. H. J.)

PETER'S PENCE (DENARIUS OF ST. PETER, or ROMESCOT), the annual voluntary contribution made by Roman Catholics for the support of the Holy See, transmitted by local bishops and administered by a special commission of cardinals. The modern practice derives from the 19th century. During Pius IX's exile in France at the time of the 1848 revolution in Italy, a subsidy called *le denier de St. Pierre* was collected for him by a Catholic committee. In 1860 another collection was taken up at Vienna by a similar group, the Confraternity of St. Michael. This custom was derived from that begun in England in the 8th century, whereby each householder paid, on St. Peter's Day (Aug. 1) an annual tax of one penny for the support of the pope. The first written evidence for it appears in 1027 in a letter of King Canute to his people, which indicates that the custom was then well established. The exact origin is uncertain. West Saxon writers ascribe it to Ina, king of Wessex; Mercian tradition attributes it to Offa, king of Mercia (both 8th century). The tax was fairly regularly paid by the English until Henry VIII abolished it in 1534.

(G. F. D.)

PETHICK-LAWRENCE, FREDERICK WILLIAM PETHICK-LAWRENCE, BARON (1871–1961), British Labour statesman, secretary of state for India and Burma from 1945 to 1947, and a leader of the women's suffrage movement, was born in London on Dec. 28, 1871, the son of Alfred Lawrence. Educated at Eton and Trinity College, Cambridge, he had a distinguished academic career and was a noted athlete. In 1897 he became a fellow of Trinity, but soon turned to social work in the east end of London. Possessing private means, in 1901 he gained control of the *Echo* evening newspaper and was editor from 1902 to 1905. In 1901 he married Emmeline Pethick and added his wife's name to his own. A devoted couple, they became leaders in the agitation for women's suffrage. Pethick-Lawrence supported the cause with great devotion and generosity and in 1912, after a demonstration in London, was sentenced to nine months' imprisonment.

Elected to Parliament in 1923 as Labour member for West

Leicester, he became financial secretary to the treasury in 1929, but declined to support Ramsay MacDonald's coalition national government in 1931 and lost his seat. During these years he wrote and spoke on financial and economic questions and made a close study of the problem of India. He returned to Parliament as member for East Edinburgh in 1935. When Clement Attlee formed his Labour government in 1945, Pethick-Lawrence became secretary of state for India and Burma and accepted a peerage. He led the cabinet mission that visited India in March 1946 and paved the way for independence. Retiring at his own wish in 1947, he continued to be prominent in the House of Lords. Completely unselfish, he had the affection of his colleagues and was respected by all. He died in London on Sept. 10, 1961. His works include *This Gold Crisis* (1931) and an autobiography, *Fate Has Been Kind* (1943).

See V. Brittain, *Pethick-Lawrence* (1963). (A.)

PÉTION, ALEXANDRE SABÈS (1770–1818), Haitian liberator and president. Born at Port-au-Prince, the son of a wealthy French colonist and a mulatto, he received more education than most of his class. He served in the French colonial army before the revolution and then joined the revolutionary troops of Toussaint l'Ouverture (*q.v.*) and later those of the mulatto general André Rigaud. Fleeing to France after Toussaint defeated Rigaud, Pétion returned in 1802 with the French Army but then became one of the first native officers to revolt against France, in 1803. He was a leader in the revolt against the dictator Jean Jacques Dessalines (*q.v.*) in 1806, and when Henry Christophe (*q.v.*) set up a separate state in Northern Haiti, Pétion was elected president of Southern Haiti, in 1807. He was reelected in 1811 and made president for life in 1816, dying in office in 1818. He is remembered in Spanish America for his help to Simón Bolívar in the darkest days of that area's war for independence.

(D. G. Mo.)

PÉTION (DE VILLENEUVE), JÉRÔME (1756–1794), a political figure of the French Revolution, was born at Chartres on Jan. 3, 1756, the son of a lawyer. After practice as an advocate, he became the representative at Chartres of the intendant of Orléans. Then the third estate of the *bailliage* of Chartres sent him to the Estates-General of 1789. Sitting with Robespierre on the extreme left of the Constituent Assembly, he won a name for probity and strength of character, but his ability fell short of his reputation. When the Constituent Assembly dissolved itself, he and Robespierre received an ovation from the people; and in November 1791, Pétion was elected mayor of Paris.

When the Girondins, on June 20, 1792, organized an armed demonstration to intimidate Louis XVI, Pétion at first ignored the efforts of the directory of the Seine *départements* to prevent it; but finally he went to the Tuileries to protect the king and persuaded the mob to withdraw. As his relations with the directory of the *départements* grew worse, he was suspended by it from his mayoral functions on July 6; and the king confirmed this suspension on July 12. The Legislative Assembly quashed the suspension, and on Aug. 3 Pétion led a deputation from the Paris sections to ask the Assembly to depose the king. Yet on Aug. 10, during the insurrection that led to the suspension of the monarchy, Pétion had himself put under house arrest by the Commune, to avoid having to take a decision. The Commune maintained him in his functions.

Elected deputy for Eure-et-Loir, Pétion was the first president of the Convention; and at the end of September 1792 he also presided at the Jacobin Club. But his popularity waned after his refusal, in October, to accept reelection as mayor of Paris. Objecting to the supremacy of Paris over the *départements*, he rallied to the Girondins, fell under Mme Roland's influence and began to attack Robespierre. At the trial of Louis XVI he voted for appeal to the people, for the death sentence, and for reprieve.

Having encouraged the Convention to withstand a new attempt at insurrection (March 10, 1793), Pétion was one of the 22 Girondins whom, on April 15, the commissaries of the Paris sections asked the Convention to expel; and at the coup of June 2 he was expelled. Escaping arrest, he made his way first to Caen, then to Brittany, then by sea to the Gironde, where he and his friends expected a welcome. While some of the refugees were arrested and executed, Pétion and F. N. L. Buzot took to the woods before killing themselves outside a hamlet in the Commune of St. Magne. Their bodies, half-devoured by wolves, were found on June 18, 1794. (A. So.)

PETIPA, MARIUS (1819–1910), French dancer and choreographer who worked for nearly 60 years at the Imperial Theatre in St. Petersburg and had a profound influence on the nature of modern classical Russian ballet. He collaborated with Tchaikovsky on *The Nutcracker* (choreographed by his assistant, Lev Ivanov) and *The Sleeping Beauty*.

Petipa, who was born in Marseilles on March 11, 1819, and his brother Lucien (later principal dancer at the Paris Opéra) received their early training from their father, Jean, a ballet master long active in Brussels. Marius danced in Belgium, France, and the United States (he appeared in New York in 1839) before accepting an engagement in Spain, where he gathered material for ballets later produced in Russia.

He made his St. Petersburg debut in 1847 in *Paquita* and staged his first original ballet, *Un Mariage sous la régence*, there in 1858. For his wife, the ballerina Marie Surovschikova, he created *Le Marché des innocents* (1859). His first outstanding success was *La Fille du pharaon* (1862). Later, after being appointed choreographer in 1862 and chief choreographer in 1869, he produced more than 60 ballets. His versions of *Swan Lake, Raymonda,* and *Giselle* have been revived frequently. After the death of his first wife, Petipa married another dancer, Lubov Leonidova. He died at Gurzuf, Russia, on June 2, 1910.

PETITION, RIGHT OF, a legal and political term denoting the right of a citizen or subject to appeal to his government for redress of grievances.

Great Britain.—Petition in Great Britain may be made to the crown or its officers, or to either house of parliament or in certain cases to courts of justice. The right of petitioning the crown was recognized indirectly as early as Magna Carta in the famous clause, *Nulli vendemus, nulli negabimus aut differemus, rectum vel justitiam* ("To no one will we sell, to no one will we deny or delay, right or justice" art. 40.), and directly at various later periods, *e.g.*, in the articles of the House of Commons assented to by Henry IV, by which the king was to assign two days in the week for petitions (*Rot. Parl.* 8 Hen. IV, p. 585). In 1688 the case of the seven bishops, who were charged with seditious libel for petitioning the king but were found not guilty, confirmed the right, and finally the Bill of Rights in 1689 declared that, "it is the right of the subjects to petition the king, and all commitments and prosecutions for such petitioning are illegal." At first, petitions to the crown appear to have been for the redress of private and local grievances, or for remedies which the courts of law could not grant. As equity grew into a system, petitions of this kind not seeking legislative remedies tended to become superseded by bills in chancery. Statutes were originally drawn up by the judges at the close of the session of Parliament from the petitions of the Commons and the answers of the crown. Under this system of drafting, it was found that the tenor of the petition and answer were not always stated correctly. To obviate this inconvenience, demands for legislation came in the reign of Henry VI to be drawn up in the form of bills which the crown could accept or reject, but could not alter. In the same reign, the words "by authority of parliament" were added to the words of enactment, and from the time of Henry VII public legislation has been by bill and not by petition. The right to petition is thus closely interwoven with the history of parliamentary legislation.

Petitions to either house of the legislature seem to have been later in origin than petitions to the crown. They are not referred to in the Bill of Rights, but the right of petition is a convention of the constitution. Petitions to the House of Lords or the whole Parliament can be traced back to Henry III. No petition to the Commons has been found earlier than Richard II, but from the time of Henry IV petitions to the Commons were freely made.

The political importance of petitioning dates from about the reign of Charles I. The development of the practice of petitioning had proceeded so far in the reign of Charles II as to lead to the passing in 1661 of an act (13 Car. II St. 1 c. 5) against "tumultuous petitioning:" It provided that no petition or address should be presented to the king or either house of Parliament by more than 10 persons; nor should anyone procure more than 20 persons to consent or set their hands to any petition for alteration of matters established by law in church or state, unless with the previous order of three justices of the county or the major part of the grand jury.

Up to 1688, petitions to either house usually dealt only with some specific grievance. From that time dates the practice of petitioning with regard to general measures of public policy. Petitioning as a device of political agitation became very common in the later 18th century, and afforded a basis for radical organizations seeking parliamentary reform. The number of petitions presented annually increased 25-fold between 1780 and 1830, and culminated in the monster petitions for electoral reform in 1830–32 and the great Chartist petitions of 1839, 1842 and 1848. (*See* CHARTISM.)

In modern times, the presentation of public petitions plays little effective part in parliamentary affairs. Most fail to conform to the very strict tests of technical validity. Petitions to the Houses of Lords or Commons must be framed in the form prescribed by the standing orders, must be properly superscribed and must conclude with a prayer. Petitions to the Commons must be in writing, must contain none but genuine signatures and must be free from disrespectful language or imputations upon any tribunal or constituted authority. They must be presented by a member of the House, except petitions to the House of Commons from the corporation of London, which may be presented at the bar by the sheriffs. The rules as to petitions to the House of Lords are similar. Applications for leave to bring before either house bills for private or local and personal matters must under the standing orders of both houses be made by petition, and the same rule obtains as to applications for leave to be heard in opposition to such bills. (X.; D. TN.)

United States.—The right under the 1st amendment to the U.S. Constitution to petition the government for redress of grievances is one of the basic guarantees of U.S. liberty, being closely associated historically with freedom of assembly. The political theory of the American Revolutionary era emphasized strongly that the colonists were entitled to all the historic guarantees of English liberty. As one such right, freedom of petition found its way into several of the state constitutions drafted in the Revolutionary period, while Thomas Jefferson in the Declaration of Independence significantly listed the flouting of "petitions for redress" as a major grievance against the British king. In 1789, the 1st Congress incorporated the right of petition, along with freedom of religion, press, speech and assembly, in the first of a series of proposed amendments submitted to the states. Ratification of the 1st amendment thus made freedom of petition an integral part of the so-called federal Bill of Rights. Thereafter, virtually all the states incorporated guarantees of petition in their own constitutions.

The right to petition has been exercised constantly in U.S. political life, both Congress and the various state legislatures having well-defined procedures for receiving and acting upon materials of this kind.

Virtually the only constitutional argument of consequence involving petition occurred when the national House of Representatives in 1836 adopted a so-called "gag rule" against the receipt of abolitionist petitions condemning the institution of slavery. Anti-slavery Whigs under the leadership of John Quincy Adams thereafter attacked the "gag rule" (*see* GAG RULES) as a violation of the right of petition as guaranteed in the 1st amendment and finally forced its repeal in 1844.

PETITION OF RIGHT refers to a petition by a subject asserting a right against the English crown, as in the Petition of Right of 1628, a petition of Parliament to Charles I complaining of a series of breaches of law. Until 1947 the term referred to the procedure by which a subject could sue the crown. This was abolished by the Crown Proceedings Act of 1947.

At common law the crown—a term which is, in constitutional law, merely an abstraction for the sovereign in his official capacity —could not be sued in the king's courts. The king was, historically, the supreme lord of those courts, administering justice in them between his subjects; and as the supreme lord he was not subject to their jurisdiction. Naturally his writs could not run against himself. Hence it became a practice, whenever a subject's real or personal property had come into the possession of the king or his servants without legal title, for the subject to "petition" the King in Council, praying for its restoration. The king then might or might not, at his discretion, refer the suppliant's petition to one of his courts, usually to the old Court of Exchequer, with a writ directing the judges to do what was just (*fiat justitia*).

Originally the scope of a petition of right was confined to issues of fact. When the subject relied on some title appearing by record, such as letters patent issued by the crown, he could proceed by what was known as a *monstrans de droit*. There was another method, known as a traverse of inquest of office, by which a subject might in certain cases challenge the king's title to land or chattels. These practices were consolidated in the Petition of Right Act of 1861, which regulated procedure without creating new rights or abolishing old prerogatives. It provided that anyone seeking to sue the crown should file a petition, in effect a statement of claim, with the home secretary, who invariably referred it to the attorney general for advice. If the latter advised that there was a substantial "cause for action," the home secretary endorsed it with his *fiat justitia*. If he refused it, the subject was without remedy. In practice the *fiat* was rarely refused, unless the claim appeared to be a purely frivolous one. Nonetheless, in such a case the executive, not the courts, performed a judicial function—namely that of deciding whether there was a reasonable cause for action—that in the case of litigation between subject and subject was entrusted solely to the judiciary. The grant of the *fiat* in no way prejudged the issue to be tried, and the crown was entirely free, after having granted it, to plead before the courts that action did not lie.

Once the *fiat* was granted, the proceedings entered the stage of an ordinary action between subject and subject, although particular privileges, not present in ordinary actions, existed on both sides. Among the crown's prerogatives the most important was "That the Crown is entitled to full discovery, and that the subject as against the Crown is not" (Chief Justice Sir John Rigby in *Attorney-General* v. *Newcastle on Tyne Corporation*, 1897, 2 Q.B. 384). This meant that the suppliant could not, as in an ordinary action between subject and subject, compel the other party, *i.e.*, the crown, to produce for inspection documents which might be essential to prove his case. The crown might also claim "privilege" in respect of any attempt by the suppliant to compel his witness, whether in the service of the crown or not, to disclose "matter of state." These prerogatives, among others, constituted a great advantage for the crown over the suppliant; but the latter did enjoy special privilege in certain matters, notably freedom from denial on the basis of the Limitation acts, by which action of contract must be brought within specified periods. That the suppliant might not of right demand trial by jury worked no great hardship: the question was independently determined by the judge.

Judgment was given in the ordinary manner, but the execution of the judgment was quite another matter. The courts could not decree execution against the crown and its servants. The act of 1861 provided, however, that, where judgment was in favour of the suppliant, it should be certified by the court to the treasury, which should then satisfy it out of public funds.

The rule of law that "the king can do no wrong" formerly directed that the king could not, even under a petition of right, be sued for the tortious actions of his servants. This immunity was waived in the Crown Proceedings Act of 1947, which established an entirely new pattern for remedies against the crown.

PETITOT, JEAN (1607–1691), French-Swiss painter of miniature portraits in enamel, was born in Geneva, the son of the sculptor Faulle Petitot. He was apprenticed to a jeweler from 1622 to 1626, but about 1633 he went to France, and there probably became the pupil of Jean and Henri Toutin, the originators of the art of painting miniature portraits in enamel. In or before 1637 Petitot went to England, where he was patronized by Charles I and his court; a handful of miniatures are known from this period, all copies of portraits by Sir Anthony Van Dyck. Petitot formed high expectations of his stay in England but the Civil War disappointed his hopes, and he returned to France. There he enjoyed for many years the patronage of Louis XIV and his courtiers. A complete catalogue of Petitot's enamels would comprise many authentic portraits of the king, his family, and the most celebrated figures in his entourage, the majority based upon paintings by fashionable artists. Petitot worked in partnership with Jacques Bordier until the latter's death in 1684. On the revocation of the Edict of Nantes in 1685, Petitot, as a Protestant, was imprisoned until, worn out by fever and old age, he signed a recantation. In 1687 he was allowed to return to Geneva and was received back into the Reformed Church. He died at Vevey, Switz., in 1691.

Although priority in the discovery of the art of painting enamel miniature portraits belongs to the Toutins, it was Petitot who by his incomparable facility raised the art to a pitch never surpassed. While relying primarily on original portraits by others, he preserved to a remarkable degree the character of the presentation which he was transforming into a small jewellike roundel. The most important collections of his works are in the Victoria and Albert Museum, London, and the Louvre, Paris. His style, much imitated in his own time, called into being a vast number of 18th- and 19th-century copies or imitations. Petitot's journal gives many details about his life.

His son JEAN LOUIS PETITOT (1653–after 1699) painted portrait enamels in a style closely resembling that of his father.

PETLYURA, SYMON (1879–1926), Ukrainian patriot who led the struggle for his country's independence in the years following the Russian Revolution, was born in Poltava on May 17 (new style; 5, old style), 1879. In 1905 he was one of the founders of the Ukrainian Social Democratic Workers' Party. He published a Socialist weekly newspaper, *Slovo* (1905–09), in Kiev, and the weekly *Ukrainskaya Zhizn* (1912–14) in Moscow. He served as an officer in the Russian Army in World War I from 1914, but after the March Revolution of 1917 he joined the Ukrainian Central Council. In July he was appointed minister of defense in the first Ukrainian government. During the German occupation of the Ukraine (February–November 1918) Petlyura was politically inactive; but by mid-November he reappeared as one of the five members of the Ukrainian directorate and as *ataman* (commander in chief) of the Ukrainian Army. During 1919 the Ukraine became the theatre of confused operations of three different armies: the national Ukrainian, the Soviet Ukrainian and the White Russian. As the leaders of the last-named two rejected the idea of an independent Ukraine, Petlyura turned for help to the newly restored Poland. On April 22, 1920, he concluded a treaty of alliance with Jozef Pilsudski, the Polish head of state; but the outcome of the campaign of that year (*see* RUSSO-POLISH WAR) was such that Poland was unable to help in creating an independent Ukraine. After some months in Warsaw, Petlyura moved with his government to Paris. On May 25, 1926, he was shot dead by Shalom Schwarzbard, who said at his trial he wanted to take revenge on Petlyura for the pogroms perpetrated on the Jews of the Ukraine—pogroms for which the *ataman* had not, however, been responsible.

PETN (pentaerythritol tetranitrate) is a powerful, sensitive high explosive and is used in medicine as a vasodilator. It was first prepared by L. Vignon and F. Gerin in 1901 but was not in systematic use prior to World War II. Its structural formula is $C(CH_2ONO_2)_4$. The manufacture involves the nitration of pentaerythritol with concentrated nitric acid and a subsequent washing to eliminate acid. Pentaerythritol, $C(CH_2OH)_4$, is synthesized by the reaction of acetaldehyde with formaldehyde, catalyzed by calcium oxide. PETN is a white crystalline powder, melting point 140° C, specific gravity 1.77. It is insoluble in water but is soluble in acetone and several other organic solvents. As an explosive it is used as an ingredient of detonators and as the charge of the detonating fuze Primacord; for use as a bursting charge of military devices it is usually mixed with other ingredients, largely TNT, to reduce its sensitivity to percussion and to make it suitable for loading by casting.

(G. B. K.)

PETŐFI, SÁNDOR (1823–1849), one of the greatest Hungarian poets, was born at Kiskörös, Jan. 1, 1823. Petőfi had an eventful youth; he studied at eight different schools, joined for a short time a group of strolling players and enlisted as a private soldier, but because of ill health was soon dismissed from the army. He traveled extensively in Hungary, mostly on foot. As a schoolboy he displayed a keen interest in the stage and in literature, and his first poem was published in 1842. After years of vicissitudes and misery, in 1844, on the recommendation of Mihály Vörösmarty, then the leading Hungarian poet, he became an assistant editor of the literary periodical *Pesti Divatlap*. His first volume of poetry, *Versek*, appeared in the same year, and made him famous at once, though the tone of his poems scandalized many. In 1847 he married Julia Szendrey who inspired his best love poems.

BY COURTESY OF THE PETOFI IRODALMI MÚZEUM, BUDAPEST

SÁNDOR PETOFI: A LITHOGRAPH FROM THE DESIGN OF M. BARABAS, 1845

Petőfi played a leading role in the literary life of the period preceding the outbreak of the Hungarian revolution of 1848. After 1847, together with Mór Jókai, he edited the magazine *Életképek*. A fervent partisan of the French Revolution, an admirer of Pierre Jean de Béranger and Hégésippe Moreau, he castigated in violent terms the social conditions of his country, attacking the privileges of the nobles and the monarchy. Politically he was an extreme radical, an inspired agitator, but he was lacking in experience and failed to obtain a seat in the diet. His poems were glowing with political passion, and one of them, "Talpra magyar" ("Rise, Hungarian"), written on the eve of the revolution, became its anthem. During the revolution he became the aide-de-camp of Gen. Jozef Bem, then head of the Transylvanian army, who had great affection for the somewhat unsoldierly but enthusiastic poet. Petőfi disappeared during the battle of Segesvár, July 31, 1849. Public opinion refused to believe in his death and for many decades hoped to see him return.

Petőfi's poetry meant a revolution in Hungarian literature. Opposed to the fashionable literary conventions and mannerisms, he introduced a direct, unpretentious style, and a clear, unorna-

mented construction adapted from national folk songs. This simplicity was the more arresting as it was used to reveal extremely subtle emotions and political or philosophical ideas. His poetry is characterized by realism, humour and descriptive power and imbued with a peculiar vigour. Of his epic poems the *János vitéz* (1845), an entrancing fairy tale, is the most popular. Petőfi's popularity has never diminished in Hungary, and were it not for the barrier of language his name would probably take its place with those of Burns and Heine in world literature. In his homeland his poetry and his personality have remained the symbols of the people's desire for freedom.

A critical edition of Petőfi's works by B. Varjas Béla was published in six volumes, 1948–56.

See J. Horváth, *Petőfi* (1922); G. Illyés, *Petőfi* (1954). (N. Ki.)

PETRA (Arabic Batra), an ancient city situated about 16 mi. (26 km.) NW of Ma'an in the south of the Hashemite Kingdom of Jordan. The city lies on the western slopes of a plateau extending from the Wadi Nemeila (Wadi an Namlah) in the north to the Wadi Sabra (Wadi as Sabrah) in the south. The terrace on which the city is built is pierced from east to west by the Wadi Musa (the valley of Moses), one of the traditional places where Moses struck the rock and where water gushed forth. The valley is enclosed by sandstone cliffs veined with every shade of red and purple to pale yellow and eroded into fantastic shapes.

The Greek name Petra ("rock") probably replaced the biblical name Sela. The site, at once accessible and secluded, appears to have been occupied from Paleolithic times as Acheulean-type tools have been found on the upper slopes. In one of the valleys an Upper Paleolithic rock shelter has been found. The Neolithic is represented by a settlement on the road to the northern suburb of Al Barid where dwelling places, flint arrowheads, and other implements have been uncovered. Nothing further of Petra is known until the Iron Age. Evidence of the occupation of the site in the 9th century B.C. has been found on the top of Umm al Bi'ar, the massif west of the temple, but this may then have served only as a place of refuge.

Traditionally Petra was the home of the Horites, who were driven out by the Edomites. These suffered a defeat by Amaziah, king of Judah, who slaughtered survivors by casting them down from the rock (probably Umm al Bi'ar). The Edomites were replaced by the Nabataeans (*q.v.*; an Arab tribe, first mentioned in the 7th century B.C. as enemies of Ashurbanipal of Assyria). They made Petra their centre, about 312 B.C., according to Diodorus Siculus, and later achieved a monopoly of the spice trade since they commanded the routes via Gaza and Damascus to Elath (Aqaba) and Al Ula (Al 'Ala). The Nabataeans had a script akin to Aramaic, but spoke Arabic.

There were constant conflicts between the Nabataeans and the Seleucids, and Petra was sacked at least on one occasion in the 3rd century B.C. In the following years the power of this Arab tribe increased, and they sacked Damascus in 85 B.C. Petra became the capital of a state extending from Jordan to the Negev and to the Mediterranean coast at Al 'Arish, Egypt. The Romans continued the struggle begun by the Seleucids, and after the Nabataean defeat of A.D. 106 Petra became part of the Roman province of Arabia, the capital of which was transferred to the Syrian Bozrah (Bostra). The city of Petra continued to flourish for some time after the Roman occupation, until changing trade routes led to the rise of Palmyra and caused its gradual commercial decline. The inhabitants became Christians, and for a short time it was the seat of a bishopric. It was already in decline at the time of the Islamic invasion in the 7th century. In the 12th century the crusaders built a castle there called Sel. Otherwise the site was occupied only by wandering tribesmen, and it was in this condition when rediscovered for the Western world by the Swiss traveler J. L. Burckhardt in 1812.

Petra is usually approached from the east by a narrow gorge known as the Sik (Wadi as Sik), 1¼ mi. (2 km.) long. It contains certain rock-cut tombs and an arch, now ruined. Al Khaznah, one of the most impressive of the monuments, is there cut in the solid rock with a columned facade. It probably dates from the 2nd century A.D. The most noteworthy features of Petra are the tombs,

FRANK HURLEY—RAPHO GUILLUMETTE

COLUMNED FACADE OF AL KHAZNAH, ONE OF THE MANY NABATAEAN ROCK-CUT TOMBS AT PETRA, PROBABLY DATING FROM THE 2ND CENTURY A.D.

often with elaborate facades, now used as dwelling places. A paved street is situated beside the Wadi Musa and has been partly reconstructed. Excavation from 1958 onward on behalf of the British School of Archaeology in Jerusalem and the American Schools of Oriental Research has added considerably to knowledge of pre-Roman Petra. Discoveries include 3rd century B.C. houses of pisé dated by coins of Aradus in Phoenicia to 290 B.C., quantities of fine Nabataean pottery, painted and plain, stone and clay incense burners, and small stone portable altars, similar to those from the Hadhramaut and Yemen. The only free-standing building is the Qasr al Bint ("Castle of the Girl"), dating from the 2nd century A.D.

At Katuleh part of a Nabataean house of the 1st century A.D. was cleared. It was built of ashlar masonry, and its walls were still standing nearly 10 ft. (3 m.) high in places. The interior had been coated with painted and molded plaster. The Romans remodeled the city evidently on a smaller scale than its Hellenistic forerunner. A study of the town walls has shown two sets, the outermost of which is the earlier. The inner wall appears to be a Roman defensive one. The area occupied appears to have been about 1½ sq.mi. (3.9 sq.km.). Many of the tombs have inscriptions in either Nabataean or Latin indicating their owners.

The principal deity of Petra was Dushara (Dhushara) who was worshiped in the form of a crude stone block or stele. In addition to their caravan trade the Nabataeans appear to have been copper miners and smelters, as fragments of copper ingots were found in the ruins of their early structures. Copper ores are found in the Wadi al'Arabah not far from Petra.

(M. V. S.-W.)

PETRARCH (Francesco Petrarca) (1304–1374), Italian poet, the first humanist and the first modern lyric poet, was born at Arezzo, July 20, 1304, son of a notary, Ser Pietro di Ser Parenzo of Incisa in Valdarno, and his wife, Eletta Canigiani. His father (who after 1312 is referred to as Petrarca, the surname which his son made famous), had been banished from Florence, on Oct. 20, 1302, probably as the result of personal differences with Albizzo Franzesi, a leader of the Blacks, and not, as his son allowed it to be understood, for political reasons, like Dante. Francesco remained at Arezzo for less than a year; then his family moved, to Incisa (where they stayed until *c.* 1310), to Pisa (where perhaps he met Dante) and finally to Avignon (1311), at that time the seat of the papacy, where his father hoped to find suitable employment. Owing to the difficulties of finding lodgings, the family settled at Carpentras nearby and there Francesco began his studies under the modest direction of Convenevole da Prato. In 1316, in obedience to his father's wishes, he went to Montpellier to study law. To this period, although they were certainly revised later, belong the earliest poems that have survived, those on the death of his mother (1318 or 1319: *Epistolae metricae*, i, 7). In 1320 he moved to Bologna and unwillingly continued his legal studies there until 1326. His knowledge and love of the classics increased and he was able to develop his acquaintance with the new vernacular poetry, perhaps even to experiment for himself. In 1326 he returned to Avignon, gave up his legal studies and took minor orders (which would allow him to enjoy benefices and canonries without ecclesiastical obligations).

For some years he enjoyed the life of the Avignon court where he soon made a name for himself thanks to the elegance of his culture and his first poetic attempts in Latin and the vernacular. His early youth, which had been mainly influenced by his love of God and virtue and his realization of the transitory nature of human affairs, was followed by a period of dissipation which coincides with the beginning of his most famous love affair (*Secretum meum*, iii, 6–7).

On April 6, 1327, in the church of Sta. Chiara, he first saw Laura, the lady who was to dominate his poetry, though not all his works, and still less his life, as the romantics would have us believe. Such critics, followed by the positivists, have consistently tried to give a face and a name to the "lady" of the *Canzoniere* (she has been identified with Laura di Audiberto di Noves who married Ugo di Sade, Laura di Sabran, Laura di Chiabau, Laura Colonna, etc.). The reaction is seen in the opposite tendency to see in Laura a pure symbol or *senhal* (in the language of Provençal poetry), a personification of intellectual beauty and truth. But neither the particular images that are woven into the *Rime* nor the accepted transfigurations and poetic structure imposed by literary tradition are able to reduce her to a symbol or an allegory. Yet it is useless to try and find out who she really was since Petrarch maintained silence about everything that concerned her civil status, as though he considered it of no importance. Laura lives only in his verse even though Petrarch drew his inspiration from a woman whom he had really known and loved.

At the invitation of Giacomo Colonna, a friend of his Bolognesi years, who had been appointed bishop of Lombez, Petrarch passed the summer of 1330 in that little Gascon town, "a most heavenly summer owing to the gaiety of the bishop and his companions," and then entered the service of Giacomo's brother, Giovanni, Cardinal Colonna, where he was to remain until 1347, "not serving a master, but rather a father or better still a most affectionate brother" (*Posteritati*). These were decisive years, crowded with travel alternating with periods of austere retirement, years of ambition but also of unpretentious, unremitting study and literary activity, particularly in the field of classical Latin (up to 1328). In 1333, he journeyed through France, Flanders, Brabant and the Rhineland. In Paris, thanks to a gift from Father Dionigi of Borgo San Sepolcro (his faithful friend and discreet confidant in spiritual matters) he was introduced to the *Confessions* of St. Augustine, a book which he was to use more and more as the breviary of his spiritual life; at Liège he transcribed, among other things, the Ciceronian oration *Pro Archia*, that great manifesto of the nature of poetry. These events seem almost to symbolize his mission as a stubborn advocate of the continuity between classical culture and the Christian message (as between a rich promise and its divine fulfillment) which justifies his position as founder and representative of European humanism and which can already be discerned in his two most ambitious and significant Latin works of this period, the *De viris* and the *Africa* (begun 1338 or 1339). And even before 1336 he had already begun to select, revise and copy those vernacular poems which he had been composing with increasing care during the preceding ten years.

The Mature Years.—Early in 1337 his dreams and aspirations which had been resolutely directed toward classical civilization found fulfillment in a visit to Rome. It was perhaps this deep emotional experience, which confirmed him in his faith, and the moral and religious doubts which had dramatically assailed him the previous year on his ascent of Mt. Ventoux with his brother Gherardo, that made him, when he returned to Provence, seek a refuge far from the restless, corrupt life of Avignon, full of memories of his most dissipated years (in 1337 his natural son Giovanni had been born). A few miles to the east he found the solitude of Vaucluse which was to serve as a retreat sacred to meditation and to poetry: his Helicon.

In Sept. 1340 there reached him simultaneous invitations from Paris and Rome to be crowned poet laureate, an honour which he had sought, not only from ambition but also in order that the rebirth of the cult of poetry might be celebrated after 1,000 years. For this reason he had no hesitation in preferring the Capitol to the Sorbonne and it was in the Capitol, on April 8, 1341, that he received a laurel wreath which he deposited as a symbolic gesture on the tomb of St. Peter.

From May 1341 until Feb. 1342 Petrarch was in Parma and later in the nearby solitude of Selvapiana; he then returned to Provence till the autumn of 1343. It is generally believed that at this time he passed through a "crisis" which, after a further period of dissipation in Avignon (his natural daughter Francesca was born in 1343), led him to a better-regulated life in which his spiritual need found expression in an intense concern for literary as well as moral problems. His inner torment, increased perhaps by his brother's decision to enter a Carthusian monastery, can be reduced to a conflict between his religious faith and his inability to adapt his own life to it: this is the situation so lucidly set out in the *Secretum* (42–43: "many times I thought to have shaken off my former yoke but it has bitten deep down to my bones . . . I shall die in my sin if help does not come from on High . . .").

It was therefore an evolution, both moral and literary, rather than a crisis, which made him realize that his love for Laura was wrong in spite of its purity and although it inspired him to do good, because it made him love his Creator for what he had created (and not the creature as the work of God) and was proof, therefore, of his attachment to this earth; an evolution which led him to break through the barriers of his too exclusive admiration for antiquity and to admit other and more authoritative voices. In the *De vita solitaria* (1346) the antinomy between classical and Christian culture appears almost completely resolved: "solitude," that great literary myth bequeathed by Petrarch to the humanist and modern worlds, becomes the point of contact between the *otium literatum* of the ancients and Christian asceticism; classical writers and heroes mingle with the prophets, saints and holy fathers, to such an extent that the first plan for the *De viris* was enlarged to include material from sacred as well as secular history.

Events which are fundamental to his biography as a man and a writer befell Petrarch during these years. He became sympathetically, even enthusiastically, interested in the efforts of Cola di Rienzo to realize the dream of popular government in Rome (an attitude which divided Petrarch ever more sharply from the curia at Avignon and in 1347 caused a break with Giovanni Cardinal Colonna). The terrible plague of 1348 caused the death of many friends including Laura herself (with poetic coincidence she died on April 6): the news reached Petrarch in Parma on May 19 and he noted it in his Virgil so that he might see it often and be reminded of the decay of all earthly goods. He met Boccaccio in Florence,

a very important meeting, awakening in Petrarch a consciousness of his cultural and moral mission. He made a pilgrimage to Rome for the jubilee year (visiting his birthplace and discovering Quintilian) in 1350, the year to which Petrarch assigns his final renunciation of the pleasures of the senses.

Between these landmarks, his life unfolded, crowded with diplomatic missions and dedicated to study during periods of meditation: in the autumn of 1343 he was in Rome and then in Naples on a mission to Queen Joanna on behalf of the Colonna family; from Dec. 1343 until Feb. 1345 he was again at Parma (where he wrote the *Rerum memorandarum*) and then at Bologna and Verona (where he made his great discovery of Cicero's letters *Ad Atticum, Ad Quintum, Ad Brutum*); toward the end of 1345 he returned to Avignon and took refuge in his beloved Vaucluse for two years of great spiritual and literary activity (*Bucolicum carmen, De vita solitaria, De otio religioso*); in Nov. 1347 he left for Italy, probably on a mission in favour of Cola (whom the May revolution had placed at the head of the Roman republic) but the fall of the tribune made him change his plans; he went to Verona and then to Parma where, except for occasional visits and missions, he remained from March 1348 to March 1349 (in Aug. 1348 he was appointed archdeacon of the cathedral). He then made a more permanent home in Padua where the lord of the city, Giacomo Novello da Carrara, had obtained a lucrative canonry for him. But Giacomo was assassinated (Dec. 19, 1350) during Petrarch's jubilee pilgrimage to Rome and since he was prevented from returning to Parma by some disagreement with the bishop and the suspicious tyranny of the Visconti family, to whom the city had been ceded, he felt himself possessed anew by a longing for Vaucluse. Neither Boccaccio's visit in April nor the offer he brought of a chair in the university to be established in Florence under his guidance were able to hold him back. He left in May 1351, reached Avignon in June and went straight to Vaucluse. This fourth retreat was particularly productive: the arrangement of the *Canzoniere*, on which he had already resumed work in 1348 at Parma and Padua, began to assume a more definitive form; the idea of forming a corpus of his letters which had first come to him perhaps as early as 1345 and certainly by 1349 took shape in his plan for the first collection, the *Familiari;* he continued to work assiduously on his collection of *Metriche* begun in 1350; he embarked on his polemic against the doctors, the bitter enemies of humane letters; and he revised and rewrote various earlier works (*De viris, Secretum*).

The death of his closest friends, the suspicions of Pope Innocent VI (who had succeeded the friendly Clement VI in Dec. 1352), and his increasingly bitter differences with the curia at Avignon, finally decided Petrarch to leave Provence and to return to his own country. From the alpine frontier of Montgenèvre he addressed it with moving eloquence: "Hail O most sacred land, beloved of God, hail land whom the good can trust, the proud must fear . . . Eagerly I return to you after so many years to live with you for ever; you will provide a haven of peace for my weary life." (*Epistolae metricae*, iii, 24). He found rooms in Milan where he remained, except for brief periods, during the next eight years (1353–61) in spite of harsh criticism for his acceptance of hospitality from ambitious tyrants and the enemies of Florence (the Visconti). Apart from the considerable missions entrusted to him by the Visconti (especially notable those to Venice in 1353 to negotiate peace with Genoa, to Mantua in 1354 and to Prague in 1356 where the emperor Charles IV accorded him royal honours, to Paris in the winter of 1361 on a visit to King John II after the peace of Bretigny), the Milanese period, the longest uninterrupted stay in one place during his whole lifetime, was one of the most fruitful. He completed the first proper edition of the *Rime*, applied himself with great fervour to the *Familiares*, made considerable progress with the *De remediis*, worked on the *Trionfi*, composed the *Invectiva* against Cardinal Jean de Caraman and the *Itinerarium* and revised and set in order with scrupulous care some of his earlier works.

Later Life.—During the spring of 1361, hoping to escape from the plague, he went to Padua on the invitation of Francesco da Carrara (son of his great friend Giacomo) remaining there until Sept. 1362 when, once more as a fugitive from the plague, he sought shelter in Venice, "the only stronghold in our times of liberty and peace and justice" (*Semilium rerum libri*, iv, 3). The *signoria* gave him a house on the Riva degli Schiavoni and Petrarch promised to bequeath all his books to the republic when he died. He was joined by his daughter Francesca with her husband the Milanese Franceschino da Brossano and their small daughter Eletta: the tranquil happiness of this little family gave great pleasure to their affectionate father. He was visited by his dearest and most famous friends (by the great chancellor Benintendi de' Ravegnani, by Paduan scholars, by Boccaccio, who in 1366 presented him with a long-desired Latin translation of the Homeric poems); he was invited to play an honourable part in the life and politics of the city; he worked peacefully but with great concentration at the definitive versions of the *Rime*, the *Familiares*, the *De remediis* and the *Seniles*. Nevertheless the insult he received from four young Averroists who called him "a good man . . . but illiterate and in fact an idiot" because he believed in Christian doctrines rather than those attributed to Aristotle, an insult which was ignored by Venetian public opinion, induced him to move back to Padua in 1367. He was to remain there until his death, dividing his time from 1370 onward between Padua and Arquà in the neighbouring Euganean hills where Francesco da Carrara had given him a little house, his last Helicon. He was still in demand as a diplomat: in April 1368 he accompanied the ruler and the bishop of Padua to meet the emperor Charles IV who was on his way to Italy as an ally of the league against the Visconti; later he was in Pavia and Milan for the marriage of Violante, daughter of Galeazzo, to Lionello the second son of the king of England; in 1370 he was called to Rome by Urban V and he set off eager to see the fulfillment of his great dream of a new Roman papacy, but was halted at Ferrara by a stroke. Yet he did not stop working; in addition to revision he composed the *De gestis Caesaris*, the *Invectiva* against Jean Hesdin and the final sections of the *Trionfi*.

Petrarch died during the night of July 18–19, 1374, when he was working in his little study at Arquà, and was found the next morning, his head resting on a manuscript of his beloved Virgil.

WORKS

Petrarch's literary production as poet, historical moralist and outstanding representative of the new culture is enormous. The chronology of his writings is somewhat complicated and uncertain and is made more so by the scrupulousness with which he revised and rewrote, often very extensively. Included here is a summary list with notes and, when they exist, a reference to better editions than those in his collected works (*Opera*, 1554 and 1581).

Latin Works.—*Epistolae Metricae.*—A collection in three books of 60 epistles in hexameters, dating from the verses on the death of his mother (1318 or 1319) and the earliest epistle of 1333 to the last letters composed between 1350 and 1354; he appears to have worked on the collection in three distinct phases, about 1350, 1357 and 1363. The subject matter is, naturally, very diverse: intimate confessions, autobiographical anecdotes, letters of consolation and exhortation, moral reflections, literary propositions and rhapsodies, descriptions, panegyrics, etc. (*Poemata minora*, edited by D. Rossetti, 1831).

Africa.—Petrarch began this work at Vaucluse in 1338 or 1339, pursued it with greater vigour at Selvapiana in 1341, returned to it frequently but intermittently after 1343 but never completed it: its various parts were gradually put together but its nine books (iv and ix are very incomplete) were published only after Petrarch's death, by Paolo Vergerio in 1396. It is an epic poem in hexameters which relates the history of the Second Punic War. The episode of Sophonisba, sacrificed to political expediency by her ardent lover King Masinissa, is both pathetic and dramatic; the famous lament of the dying Magone on the decay and misery of everything on earth (it was the only passage made available during the poet's lifetime) is strictly Petrarchan in inspiration; and this sentiment, together with a desolate perception of the fugacity of time, pervades the whole work, tempering with Christianity the Roman classicism of Livy and Cicero who are widely used as

sources and at times with too heavy a hand. (Critical edition by N. Festa, 1926.)

De viris illustribus.—The original plan of this work, begun in 1338 or 1339 and continued in 1341–43 as a series of biographies of famous Romans or people closely connected with Rome, was considerably modified between 1351 and 1353 so as to include famous men of all times beginning with Adam, thus achieving Petrarch's aim of emphasizing the continuity between the ideals of the Old Testament, of classical antiquity and of Christianity. Later he wrote fuller lives of Scipio and Caesar and finally, when he was in Padua, he took up the work again with the title *Quorundam virorum illustrium epithoma,* limiting it to 36 characters whose effigies were to be placed in a hall of Francesco da Carrara's palace; but he did not get further than the preface (the rest is the work of his disciple Lombardo della Seta who also completed the *Compendium* or *Breve compendium* of which Petrarch wrote only the first 14 biographies). (Edited by L. Razzolini, 1874–79.)

Secretum meum.—This autobiographical treatise was composed between the autumn of 1342 and the winter of 1343 and revised between 1353 and 1358. Not intended for publication, it is a fundamental work for the understanding of Petrarch's inner life. It consists of three dialogues between Petrarch and St. Augustine in the presence of Truth: in the first, Petrarch's secret infirmity is identified with a sickness of the will which makes him aspire to a nobler life while lacking the knowledge and will power to achieve it; in the second, Petrarch examines his conscience with regard to the seven deadly sins and finds himself guilty of all of them except envy, but especially of *accidia* (the theological definition of the sickness of the will discussed in the first book); in the third, Petrarch convinces himself of the sinfulness both of love (even when pure and directed towards a chaste woman) and of the desire for glory: that is, of the two great passions of his life. But he wearily declares himself unable to reform. The work constitutes a self-analysis of pitiless sincerity and precise autobiographical references at one of the decisive moments of his life. (Edited by E. Carrara, in Petrarca, *Prose,* 1955.)

De vita solitaria.—Written in 1346 and later revised and enlarged (one addition is definitely of 1371), the treatise, in two books, provides the theoretical basis and the description of one of Petrarch's essential myths, that of the "solitary life," in which man is able to enjoy the consolations of nature and study together with those of prayer. (Edited by G. Martellotti, in Petrarca, *Prose,* 1955.)

De otio religioso.—Written in 1347, it was revised and considerably enlarged in 1357. It is a treatise in two books on the advantages of the contemplative monastic life. It takes up the theme of *De vita solitaria* from a more strictly devout attitude and is tinged with a sharp nostalgia for purity and spiritual peace. (Edited by G. Rotondi, 1958.)

Familiarium rerum libri xxiv.—The idea of this collection of letters goes back to 1345 or more probably to 1349. The real work of arrangement was begun between 1351 and 1353 (up to book viii) and the final version was completed between 1359 and 1360 (up to book xix); in 1363–64 Petrarch returned to it, adding four books, and continued to work on it until 1366. It consists of a selection of 350 letters (the earliest dated 1325, the latest 1366, although the collection is supposed to end at 1361) which are of great importance for an understanding of Petrarch's life, both spiritual and active, and for the history of his decisive influence on European culture. As Martellotti has observed, these collections of letters represent the final stage of that progress from the contemplation of the world of antiquity as a means of escape from unpleasant realities to an intense preoccupation with the present, and the study of antiquity as foreshadowing the moral truths of Christianity. (Critical edition by V. Rossi and U. Bosco, 1933–42.)

De remediis utriusque fortunae.—This vast work, a part of which had been begun in 1354, had reached an advanced stage by 1360 and was finished in Oct. 1366 and published immediately. Petrarch probably returned to it later. It consists of two books containing 122 and 131 treatises, or discussions, between Reason, Pleasure and Hope and between Reason, Sorrow and Fear which contain respectively advice on how to attain good fortune and the remedies for bad, and which demonstrate the inconsistencies of pleasure and pain in a tone of bitter pessimism.

Senilium rerum libri.—Petrarch began his collection of the *Senili* after 1361 but never made a definitive arrangement as he did for the *Familiari.* The collection comprises 125 letters from 1361 to 1374 in 17 books.

Posteritati.—The first draft must be dated before 1367; there were important additions between 1370–72. It is an interesting autobiography in the form of a letter addressed to posterity, left unfinished and in draft form (it only goes up to 1351); it was to have formed the conclusion to the *Senili.* (Edited by E. Carrara and P. G. Ricci in Petrarca, *Prose,* 1955.)

De sui ipsius et multorum ignorantia.—Written 1367, published 1371, this is directed against the critics of Venice. Following St. Augustine Petrarch tries to show that rhetoric and poetry are the best spurs to moral action. (Edited by L. M. Cappelli, 1906.)

Other Latin Works: Prayers (1335–38). *Epistole sine nomine,* written 1342–58; collected 1359–60. (Edited by P. Piur, 1925.) *Rerum memorandarum libri,* 1343–45. (Crit. ed. by G. Billanovich, 1945.) *Bucolicum carmen,* 1346–48; definitive version 1364. (Edited by A. Avena, 1926.) *Salmi penitenziali,* 1347. (Edited by H. Cochin, 1929.) *Invectivarum contra medicum quendam libri,* 1352–55. (Edited by P. G. Ricci, 1950). *Invectiva contra quendam magni status hominem,* 1355. (Edited by P. G. Ricci, 1949.) *Itinerarium breve de Janua usque ad Jerusalem,* 1358 *et seq. Invectiva contra eum qui maledixit Italiae,* 1373. *Epistole varie;* 65 letters not included by Petrarch in his collections.

Italian Works.—*Rerum vulgarium fragmenta.*—This was Petrarch's title for the definitive collection of his Italian verse, his *Rime.* It consists of 366 compositions (317 sonnets, 29 *canzoni,* 9 sestine, 7 *ballate,* 4 madrigals) divided into two parts (263 poems described as *in vita Laura;* 103 *in morte Laura*). Naturally the first stage in the production of this work was the actual composition of the single poems (he did not include in the collection those written earlier than 1330); the second, before 1336, his first idea of making a selection; the third, between 1342 and 1347, the arrangement of the selected poems according to a certain criterion; the fourth, after the death of Laura, their division into two parts and the project of illustrating the story of his own soul (perhaps 142 lyrics on the period before Laura's death plus 29 after); the fifth, the first proper edition of the *Canzoniere* sent to Azzo da Carreggio in 1360 (about 174 plus 41); the sixth, a second edition in Jan. 1373 sent to Pandolfo Malatesta; the seventh, the definitive edition which is preserved in the Cod. Vat. Lat. 3195, partly autograph, partly transcribed by Giovanni Malpaghini under the poet's supervision. The choice of poems and the arrangement of the collection are governed by a most rigorous and exclusive standard of aesthetic taste, by a preference for an approximately chronological arrangement and by the poet's ever growing urge to express, through these verses which are chiefly concerned with his love for Laura, the story of his own soul, from the description of his falling in love to his anxious invocation to the Virgin; from his "youthful errors" to his realization that "all worldly pleasure is a fleeting dream"; from his love for this world to his final trust in God. The theme of his *Canzoniere* therefore, goes beyond the apparent subject matter, his love for Laura. For the first time in the history of the new poetry, lyrics are not considered as *nugae* or occasional verse as they had been from the troubadours to Boccaccio: Petrarch, in spite of frequent doubts and many changes of mind, still felt that the *schedulae* containing his verses were the threads holding together a marvelous new tapestry possessing its own unity and similar to that which he was constructing, on the Ciceronian model, from his letters. By selecting all that was most polished and at the same time most vigorous in the neo-Latin lyric tradition of the preceding two centuries, and filtering it through his new appreciation of the classics, he not only bequeathed to humanity the most limpid and yet passionate, precise yet suggestive, expression of love and grief, of the ecstasies and sorrows of man, but also created with his marvelous sensibility the form and language of the modern lyric. In fact, the history of the European lyric could be re-

counted in terms of action and reaction in the face of the Petrarchan experience. (Edited by G. Contini, 1949; commentaries by G. Carducci and S. Ferrari, 1899 and, 6th ed., 1957; edited by E. Chiorboli, 1924.)

Rime disperse.—This title (or sometimes *Extravaganti*) is used for those verses Petrarch did not include in his main collection, either because they were not good enough or because they were not addressed to Laura. The authenticity of many is doubtful, in some cases no longer accepted. (Edited by A. Solerti, 1909.)

Trionfi.—A poem in *terza rima* probably conceived and begun in 1351 in imitation of Boccaccio's *Amorosa visione* and possibly of Dante's *Divine Comedy*. It was written in sections and continually revised during the following years (the earliest certain dates, 1356–60, are of the *Trionfo d'Amore*, the latest, Feb. 1374, is written in the margin of the *Trionfo dell'Eternità*). Petrarch left it unfinished and it was published posthumously. It is an historical and symbolical vision of the great theme of the *Canzoniere* raised from the autobiographical to the universal, that is, from the story of one man alone, Petrarch, to that of man in himself, or rather of the whole of humanity in its progress from earthly passion to fulfillment in God. Love triumphs over the greatest men, but is captured by Chastity; which in its turn, in the person of Laura, is overcome by Death; which is conquered by Glory; which is itself annihilated by Time: only in God does everything of beauty and everything of value, love for Laura and love for glory, shine eternally beyond all space and time, and heaven and earth are reconciled according to Petrarch's noble and constant dream. (Critical edition ed. by K. Appel, 1901; to be read in conjunction with the new sections, *Un inedito petrarchesco*, edited by R. Weiss, 1950.)

Conclusion.—This summary of the essential events of his life and sketch of the chronological and spiritual development of his works will have sufficed to show the exceptional importance of Petrarch in the poetry and culture of modern and Christian Europe; never before, perhaps, has a writer had so rapid, so decisive and so far-reaching an influence. This "presence" was so effective because it made itself continuously felt, through his spoken and written conversations with his friends and disciples, and his prodigious achievement as the discoverer of so many of the treasures of classical learning and beauty, both in those texts which he actually found and in those which he re-established by his sensitive and accurate interpretation. Through his sublime poetry, and his profound spiritual and moral meditations, his historical visions and reconstructions and in the devoted work for humane studies by which he solved the age-old problem of the reconciliation of the classical with the Christian world, Petrarch shows how in the substantial identity of human souls God provides the opportunity for meetings and contacts, for the affirmation of the same truths in different ages and under different skies. The words of his beloved St. Augustine which, during the ascent of Mt. Ventoux, flashed before his mind's eye, "And men go to admire the high mountains and the immensity of the ocean and the course of the heavens . . . and neglect themselves," are truly symbolical of Petrarch's mission in life, of his thought and of his art. Never, since the great teachers of antiquity and the greatest fathers of the church, has man had so enthusiastic and sensitive an interpreter of his sorrows and his greatness, so subtle and so sympathetic an interpreter of his eternal uncertainty outside fulfillment in God. "I always feel a sense of unfulfillment in my heart," he wrote with Augustinian inspiration in the *Secretum*. It is for this reason that the figure of Petrarch towers over that age, from Boccaccio to Erasmus, which took its name from man, the age of humanism; for this reason that, from Bembo to Michelangelo and Ronsard, from Gongora and Milton to Klopstock, from Shelley and Heine to Leopardi, to Heredia, to D'Annunzio, the art which, better than any other, expresses with precision and yet with sensitivity the most constant and the noblest aspirations of man, sprang originally from the fount of Petrarchan inspiration.

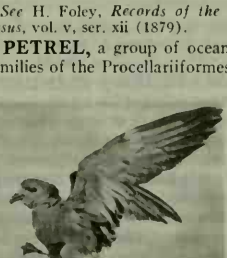
PETRE, SIR EDWARD (1631–1699), clerk to the closet to King James II of Great Britain, was born in London, the younger son of Sir Francis Petre, baronet, of Cranham. Educated in France at the Jesuit College at St. Omer, he entered the Society of Jesus in 1652 and took orders in 1671, when he returned to England. In 1679 he succeeded his elder brother in the family title and estates. In the same year he was imprisoned for suspected complicity in the "popish plot" (*see* OATES, TITUS), but he was released in 1680 by the influence of James (then duke of York). From 1679 to 1683 he was vice-provincial of the English province of the Society of Jesus. He was deep in James II's confidence, and the king's more extreme policies were attributed to him. James made many attempts to secure him a bishopric or a cardinalate, but Pope Innocent XI steadfastly refused and he had to be content with the post of clerk to the closet (1686) and membership of the privy council (1687). He is often erroneously described as James's confessor. Late in 1688 he fled abroad and had no further contact with James. He was head of the college at St. Omer from 1693 to 1697, when he was transferred to Watten in Flanders, where he died on May 15, 1699.

See H. Foley, *Records of the English Province of the Society of Jesus*, vol. v, ser. xii (1879). (J. P. K.)

PETREL, a group of oceanic birds classified in two or more families of the Procellariiformes, an order including also the albatrosses and shearwaters. There is little to support the legend that these birds, which appear to walk on the water, are named after St. Peter; the earliest English spelling (1676) was "pitteral."



ROBERT C. HERMES FROM THE NATIONAL AUDUBON SOCIETY

LEACH'S PETREL (OCEANODROMA LEUCORHOA)

Petrels make up the bulk of the Procellariiformes. The size range, from the swallowlike storm petrels (family Hydrobatidae) to the three-foot-long giant petrel (*Macronectes giganteus*), is equaled in few if any other natural groups of birds. Cosmopolitan, they occur only on salt water but extend to its uttermost

limits. Variety and abundance are greatest in higher latitudes of the southern hemisphere. Breeding grounds are almost exclusively on islands. The storm petrels, including the genera *Pelagodroma, Oceanodroma, Oceanites* and *Fregetta,* are nocturnal ashore and nest in burrows or in chinks among rocks; a few surface-breeding species occur on islands devoid of predatory enemies. The Procellariidae includes the genera *Pterodroma, Pagodroma* and *Macronectes.*

Some kinds of petrels are sedentary in the vicinity of their breeding stations. Others make very extensive migrations. For example, Wilson's petrel (*Oceanites oceanicus*), one of the seafarers' "Mother Carey's chickens," common in summer in the North Atlantic, nests in austral spring at the edge of the antarctic.

The aberrant diving petrels, composing the family Pelecanoididae, range in the southern hemisphere and breed on islands.

Petrels lay a single white egg and care for the young during their exceptionally slow growth. They feed on a wide variety of marine organisms. Only the giant petrel, which is partly a carrion eater, takes any of its food ashore or on sea ice. *See* also Albatross; Fulmar; Shearwater. (R. C. Mu.)

PETRI, OLAUS and **LAURENTIUS,** two Swedish churchmen who played decisive roles in the reformation of the Swedish church. Born at Örebro in the diocese of Strängnäs, Olaus (or Olavus) Petri (1493–1552) studied at Wittenberg (1516–18) and absorbed the reformed teaching of Luther and Melanchthon. When Gustavus Vasa was crowned king in 1523, Olaus had already attracted attention and criticism by his preaching. The Roman Catholic hierarchy were hostile to the king, who became a supporter of the reformed teaching. Laurentius Andreae, secretary and later chancellor to the king, was a friend of Olaus Petri, who preached the coronation sermon. Olaus rose in prominence and served briefly as chancellor (1531). Later he opposed the autocratic policy of the king, and both he and Andreae fell from favour and were condemned to death in 1540, the sentence being remitted for a heavy fine. Later he regained favour and was appointed pastor of Storkyrkan church in Stockholm where he died in 1552. Olaus provided most of the literature for the Swedish Reformation movement, including a Swedish New Testament (1526), hymnbook (1526), church manual (1529), the Swedish liturgy (1531), and many homiletical and polemical writings. His *Chronicle* is an important historical document.

Laurentius Petri (1499–1573) also studied at Wittenberg, returning to Sweden in 1527. He was appointed the first Protestant archbishop of Uppsala in 1531 and held this office until his death in 1573. His influence was very great, although he was less dynamic and forceful than his brother. The Swedish Bible of 1541, for which he was principally responsible, was as important for Swedish life and literature as Luther's German translation was for the German-speaking peoples. His *kyrkoordning* (church order) of 1571 defined the practice of the church, particularly its relation to government, and went far toward establishing the independence of the church from the crown which has been characteristic of most of its history.

See C. J. I. Bergendoff, *Olavus Petri and the Ecclesiastical Transformation in Sweden 1521–52* (1928); E. E. Yelverton, *An Archbishop of the Reformation* (1959). (E. M. C.)

PETRIE, SIR (WILLIAM MATTHEW) FLINDERS (1853–1942), English archaeologist remembered for his discoveries in Egypt and for introducing scientific methods of excavation, was born at Charlton, near Greenwich, on June 3, 1853. A delicate child, he was educated privately, developed an early interest in ancient weights and measures, and published *Inductive Metrology* (1875). Between 1875 and 1880 he studied sites in Britain, including Stonehenge. A long series of surveys and excavations in Egypt began (1880) with the pyramids of Giza and proceeded to the temple of Tanis (1884), the Greek city of Naukratis in the Nile delta (1885), and Daphnae and other towns (1886). Between 1888 and 1890 he worked in Al Fayyum, principally at Hawara, Illahun, and Ghurab. He next explored and excavated the pyramid and temple of Maydum. In 1894 he discovered the painted pavement at Tell el Amarna and then excavated the town of Coptos (Qift; 1895), the predynastic site of Nakada (1896), and a series of temples at Thebes (1897). From 1898–1904 he explored the great necropolis of Abydos (*q.v.*), discovering the royal tombs or cenotaphs of the earliest dynasties, and the antiquities of Dandarah. Subsequently he dug at Memphis and again in Al Fayyum, where he made a rich find of 12th-dynasty jewelry (housed since 1919 in the Metropolitan Museum of Art, New York). In 1922 Egyptian laws relating to the antiquities were made much more strict, and Petrie turned to Palestine, where he continued to excavate until 1938.

From 1892 to 1933 he was Edwards professor of Egyptology at University College, London. His excavations between 1881 and 1906 were carried out for the Egypt Exploration Fund and for private subscribers. In 1894 he founded his own fund-raising and publishing medium, the Egyptian Research Account, renamed in 1905 the British School of Archaeology in Egypt; it was dissolved in 1954.

Petrie published more than 40 large quarto volumes with numerous plates. His many books for popular reading include an autobiography, *Seventy Years in Archaeology* (1931). Essentially a practical fieldworker of great ability, he made contributions of the highest value, but had no flair for research in epigraphy. He was prone to base his theories on inadequate premises: notably his views on chronology, which are not accepted by most scholars (*see* Alphabet: *Origin*). Petrie was knighted in 1923; he died at Jerusalem on July 28, 1942.

PETROCHEMICALS, in the strictest sense, are chemicals derived wholly or partially from petroleum or natural gas. The definition, however, has been broadened to include the whole range of aliphatic, aromatic, and naphthenic organic chemicals, as well as carbon black and inorganic materials such as sulfur and ammonia. In many instances, a specific chemical included among the petrochemicals may also be obtainable from other sources, such as coal, coke, or vegetable products. For example, materials such as benzene and naphthalene can be made from either petroleum or coal, while ethyl alcohol may be of petrochemical or vegetable origin. This not only makes it difficult to categorize a specific substance as petrochemical or nonpetrochemical but also creates problems in making statistical analyses of the industry.

Petrochemicals find application in such diverse industries as agriculture; food processing; detergent, automobile, and paint manufacture; building construction; textiles; and synthetic rubber production. For example, a typical U.S. automobile in the 1960s utilized 11 basic polymers of petrochemical origin for more than 180 plastic parts. Consumption of plastics per vehicle amounted to 28–30 lb. In another area, the construction industry, petrochemicals found application in protective and decorative coatings, flooring, adhesives, electrical equipment, tiles and fixtures, panels and laminations, piping, moisture barriers, insulation, and roofing. Here, as in the automobile industry, many of the petrochemicals used were plastics or resins.

Development in the United States.—Any discussion of the history of the petrochemical industry necessarily begins with events in the United States, which was the cradle of this worldwide industry. The earliest activities came during World War I, when there were shortages of many chemicals needed for military and civilian uses. Among the more critical materials in short supply was toluene, which was required for the manufacture of explosives. To augment toluene supplies, several petroleum companies carried out thermal cracking operations on selected petroleum fractions and recovered small amounts of toluene and other aromatics. After the war, demands for toluene lessened, prices declined, and the petroleum-based product could not compete economically with materials available from the coking industry. Consequently, interest in petroleum-derived aromatics became dormant and remained so until World War II.

In contrast, interest in the production of aliphatics from petroleum prospered after the war. The production of isopropanol from propylene reached commercial proportions during 1919–20. The thermal cracking of liquid petroleum fractions and propane to pro-

duce ethylene became commercially feasible, and derivatives of this olefin made appearances on the American market in the early 1920s.

Ethylene and the other lower olefins, propylene and butylene, continued as the primary raw materials for petrochemicals during the 1920s and 1930s. One of the outstanding developments during this period was the chlorhydrin process for converting ethylene to ethylene glycol, which found a large market as an antifreeze for liquid-cooled automobile and aircraft engines.

By the end of the 1930s the petrochemical industry was gaining considerable momentum. Petroleum refining had reached a very large scale, making available a virtually unlimited supply of hydrocarbon raw materials. Research and product development activities were being carried out at a rapid pace. By 1940 many new petrochemicals, and the new chemical and engineering technologies associated with them, had become commercially successful. Thus, when the United States became involved in World War II, the petrochemical industry was in an advantageous position to make its contribution to the war effort. The huge demands for aviation fuel, rubber, plastics, explosives, fertilizer, solvents, detergents, etc., led to crash programs to create entirely new production techniques and facilities. Outstanding among these was the development of synthetic rubber, based on petroleum-derived olefins and diolefins, and the extension of petroleum refining operations to produce basic aromatic raw materials, including toluene for trinitrotoluene (TNT) manufacture. In 1944, at the peak of World War II, toluene production from petroleum sources reached approximately 166,000,000 gal., while only about 38,000,000 gal. were produced from coal. Thus, the area of aromatic chemicals was opened to the petrochemical industry.

After World War II, developments in the fields of plastics, man-made fibres, synthetic rubber, detergents, and chemical fertilizers were of most importance, especially the large-scale operations for the production of polyolefins such as polyethylene and the development of processes for the manufacture of stereospecific polyolefins. In the synthetic rubber industry, the development of stereospecific polymers of butadiene and isoprene and of copolymers of ethylene and propylene were significant contributions. Man-made fibres based on the nylons, which appeared commercially in 1939–40 and were reserved primarily for military applications during World War II, entered the civilian market after the war with astounding success. In addition, new fibres, such as those based on polymers of acrylonitrile (Acrilan, Orlon, Creslan, Zefran, Dynel, Verel, etc.), terephthalic acid and ethylene glycol (Dacron, Kodel, Vycron), and vinylidene chloride (Saran, Velon, Rovana, etc.) were introduced on a commercial scale. These fibres provided significant competition to such established materials as wool, cotton, and rayon.

Synthetic detergents gained consumer acceptance during World War II when the availability of soaps based on natural fats and oils was limited. Consumption of detergents expanded rapidly in the postwar period and soon surpassed the consumption of soap. Many products involving a wide variety of raw materials, largely based on petroleum, were introduced. But the domination of the detergent industry by synthetic products resulted in a shortage of glycerine, which previously had been supplied exclusively as a by-product of the soap industry. To alleviate this situation, a process to manufacture glycerine synthetically was developed; thus glycerine became a petrochemical.

Encouraged by demands of a rapidly expanding, ammonia-based fertilizer industry, producers of hydrogen derived from petroleum and natural gas turned this into a large-volume commercial product. Catalytic reforming operations, carried out by the petroleum industry in the manufacture of high-octane motor fuels, produced quantities of by-product hydrogen that were employed in the manufacture of synthetic ammonia. Since these sources of hydrogen were inadequate or, in many instances, not conveniently available, other sources, based on the partial oxidation or reforming of petroleum hydrocarbons or natural gas, were established to provide an essentially unlimited supply. Petrochemical hydrogen, the key to low-cost, ammonia-based fertilizers, provided hope of improving the food supply available to many undernourished peoples of the world.

Other products and processes that reached commercial significance in the period after World War II included epoxy resins, polyurethanes, polyacetals, polycarbonates, and the production of oxygenated chemicals by the controlled direct oxidation of propane and butane with air.

Development in Other Countries.—In comparison to activities in the United States, petrochemical operations in the rest of the world prior to World War II were negligible. Western Europe, centre of a highly-developed chemical industry based on its coal supplies, suffered a lack of developed petroleum or natural gas deposits and thus was not encouraged to turn to petroleum as a source of raw materials. Development of the petrochemical industry in Western Europe therefore hinged on the importation of large quantities of crude oil and the construction of refineries to process it. This occurred after World War II when discoveries of tremendous quantities of crude oil in the Middle East and North Africa provided convenient, low-cost sources for Europe's growing energy requirements. The first significant petrochemical operations were started in the United Kingdom in 1950–51. These soon were followed by the introduction of petrochemical activities in Italy, France, and West Germany. Developments in Italy and France were encouraged by the availability of significant indigenous natural gas deposits. Later, the petrochemical industry was established in the Netherlands, which enjoyed a strategic geographic location in the European Common Market and had large natural gas deposits.

Developments in Japan were notably rapid. As in Western Europe, petrochemical operations had to await development of petroleum refining activities based on imported crude oil. Thus the first facilities in Japan were not completed until 1957, but swift growth was seen thereafter.

Although activities in the United States, Western Europe, and Japan have been mentioned specifically, progress in other countries such as Canada and Australia was almost equally significant. Members of the Communist bloc of nations made a determined effort to expand their petrochemical activities. In general, petrochemical development in areas outside the United States followed the pattern established in that country, with initial operations based on paraffinic or olefinic raw materials.

Growth of the Industry.—Specific information on the output of petrochemicals in three major producing areas of the world, the United States, Western Europe, and Japan, indicates the phenomenal vitality of this industry. Growth in the United States, for example, increased over thirteenfold in the two decades following World War II, while plant investment increased more than 17 times. This rapid expansion was attributable to several factors, including (1) general growth in the economy and population of the countries involved; (2) replacement or supplementation of alternate raw materials derived from coal and agricultural products by lower cost, more conveniently available raw materials derived from petroleum or natural gas; and (3) development of new products which establish entirely new markets or displace alternative products from an established market.

The first factor needs no explanation, being related to an increased level of national incomes, construction activity, demand for consumer goods, etc. The second factor involves the replacement or supplementation of raw materials. For example, ethyl alcohol produced by fermentation of agricultural products supplied the major portion of the demand for this product before World War II. In the meantime, processes for the derivation of ethyl alcohol from petroleum-based ethylene were being perfected. These processes proved to be more economical than fermentation and thus synthetic ethyl alcohol largely replaced natural or fermentation ethyl alcohol for industrial uses in the United States. Numerous other products experienced a similar shift, from natural to synthetic, in the major source of associated raw materials, including benzene, toluene, xylene, methanol, ammonia, and rubber.

An outstanding example of a development mentioned above as the third factor contributing to the growth of the petrochemical industry is polyethylene. Production of this remarkable plastic material in the United States increased by a factor of 2,000 in a 20-year period. Although some of the growth in markets for

polyethylene was accounted for by the substitution of this plastic for metals and other materials in established applications, entirely new applications utilizing its unique properties also made significant contributions.

Location of the Industry.—The factors which establish specific geographic areas as centres for petrochemical operations are essentially the same as those controlling the location of other industries, including availability of raw materials, availability of markets, labour costs, construction costs, transportation facilities, and fuel and utilities costs. Usually a combination of these factors is involved.

In the United States, abundant raw materials in Texas and Louisiana was the dominant factor in establishing the Gulf Coast as the leading petrochemical production area. Supplementary factors included low construction, fuel, and utility costs, as well as the availability of low-cost water transportation. The primary factor encouraging locations in other areas of the United States having significant concentrations of petrochemical activity—California, the Midwest, and Middle Atlantic states—was the presence of large consumer markets. Of course, the availability of raw materials from petroleum refining operations in these areas was also a positive factor.

In Western Europe, Belgium, England, France, West Germany, Italy, and the Netherlands contain the main centres of production. In general, sites having access to good harbours and navigable waterways were favoured because of the industry's dependence upon imported crude oil or feedstocks and because of the wider markets available from these locations.

PETRODVORETS (formerly PETERGOF or PETERHOF), a town in Leningrad *oblast* of the Russian Soviet Federated Socialist Republic, U.S.S.R., and administratively under the Leningrad City Council, stands on the southern shore of the Gulf of Finland, 18 mi. (29 km.) W of Leningrad. The town has grown up round the palace and gardens built for Peter the Great in 1721. The palace, designed by J. B. A. Leblond and enlarged by Bartolomeo Rastrelli in 1752, was destroyed in World War II, but the magnificent gardens, with their 130 fountains and many pavilions, have been restored. Of special note are the Grand Cascade and the Samson fountain. (R. A. F.)

PETROGRAD: *see* LENINGRAD.

PETROKREPOST (formerly SHLISSELBURG; *Ger.* SCHLÜSSELBURG), a town in Leningrad *oblast* of the Russian Soviet Federated Socialist Republic, U.S.S.R., lies 25 mi. (40 km.) E of Leningrad, on the south bank of the Neva where it flows out of Lake Ladoga. The place was founded by the Republic of Novgorod in 1323, when it was known as Oreshek. Later the Swedish fortress of Noteborg was established there. Its capture in 1702 by Peter the Great was the preliminary to the foundation of St. Petersburg (now Leningrad). Renamed Shlisselburg, it served as the key fortress on the eastern side of St. Petersburg, and later as a prison. The terminus of the Ladoga lateral canals, the town has shipbuilding and repair yards. It was damaged during World War II, when it played an important role in the defense of Leningrad. The town was given its present name in 1944. (R. A. F.)

PETROL ENGINE: *see* INTERNAL-COMBUSTION ENGINE.

PETROLEUM is a mixture of gaseous, liquid, and solid hydrocarbons found in varying amounts in sedimentary rock deposits throughout the world. In its crude state petroleum is practically useless. When refined it supplies fuels, lubricants, illuminants, solvents, surfacing materials, and many other products. The fuels derived from it account for half the world's total supply of energy and are used not only to power the engines of automobiles, tractors, trucks, ships, airplanes, and missiles but also to heat buildings. Petroleum lubricates machines, and petroleum cutting oils make possible much of the drilling and grinding basic to mass production. Asphalt from petroleum covers floors, roofs, and highways. Either directly by combustion, or indirectly through the generation of electricity, petroleum supplies many people of the world with artificial light. Petroleum products are also used in man-made fibres for clothing; synthetic rubber for tires and other uses; cleansing agents, such as soap and detergents; paints and plastics; and numerous ingredients used in the production of fertilizers, insecticides, medicines, etc., and for food processing. In peacetime such applications have multiplied as scientists and engineers have developed new processes, and the further processing of by-products has given rise to a whole new industry, petrochemicals (*q.v.*). Every day the world consumes nearly 1,000,000,000 gal. of petroleum, which is thus the single most important item of international trade. Because large capital resources and continuous fresh investment are required, it is usually large public or private corporations that explore for, produce, transport, refine, and market crude petroleum and its products.

World Wars I and II demonstrated petroleum's vital importance. World War I focused attention on petroleum as a fuel and lubricant, and World War II on its additional role as a raw material in the manufacture of synthetic rubber, TNT, waterproofing greases for amphibious operations, fuels for flamethrowers, and incendiary materials.

Because it is indispensable in peace and war, crude petroleum is sought by individuals and by nations. Access to petroleum reserves is a constant concern of commercial and governmental policy. Petroleum has entered into politics and politics into petroleum.

Petroleum has also promoted economic development by bringing income for investment and social welfare to the producing countries (many less-developed countries, notably Venezuela and Kuwait, have made great progress as a result of petroleum revenues) and by providing a relatively inexpensive source of energy in areas where other energy sources are nonexistent or costly.

I. CHARACTERISTICS OF CRUDE PETROLEUM

A. PHYSICAL CHARACTERISTICS

Many scientists believe petroleum was formed from the remains of tiny aquatic plants and animals hundreds of millions of years

ago when the sea covered large areas of what are now landmasses. The animals and plants lived and died in countless numbers, sinking to the sea bed where they mixed with mud and sand in layers called marine sediment. Later, these sedimentary layers were covered by more mud and sand, which finally turned into rock. As ages passed the sea withdrew, the earth's crust heaved and buckled, burying the sedimentary deposits, and the heat and pressure caused by the overlying rock, together with decomposition of the organic life, formed oil from the animals and plants in the deep-buried layers. Petroleum is thus called a "fossil" fuel because, like natural gas and coal, it is derived from organic material. It is also commonly referred to as a "mineral" oil since it lies in the pores of underground sedimentary rocks or sand and is popularly linked with the minerals.

Characteristics of Representative Crude Oils

Origin	Field	Specific gravity Water=1.000	Colour	Depth of reservoir (ft.)	Approximate physical composition (%)*				Chemical base
					Gasoline and gas	Kerosene	Gas oil	Residuum	
California	Coalinga-Guijaral Hills	0.858	greenish black	6,814–6,908	36.6	4.4	36.0	23.0	intermediate

*The definitions of the products vary somewhat with location. †Not available.
Sources: A. E. Dunstan (ed.), *The Science of Petroleum*, vol. ii, p. 847; vol. v, part i (*Crude Oils*), pp. 8–23, 28, 30–34, London, Oxford University Press (1938 and 1950).

Crude petroleum contains thousands of different chemical compounds, ranging from gases to semisolid materials such as asphalt and paraffin wax. At the extreme pressure exerted underground, the gases are dissolved within the heavier components, but upon reaching the surface they may vaporize. When separated, they are called natural gas (*see* GAS INDUSTRY). Likewise, paraffin wax is dissolved in the crude petroleum, although it too may separate when cooled at the surface.

Physically, crude petroleum is a mixture of compounds boiling at different temperatures. The fraction of lightest specific gravity, comprising the gases, boils below atmospheric temperature. The next heaviest fraction, that which is normally refined into gasoline (*q.v.*), boils between roughly 30°–200° C (85°–390° F). The fraction boiling between about 140°–300° C (285°–570° F) is called kerosene (*q.v.*), while that boiling above about 300° C is called gas oil, because it was once used as a raw material in fuel-gas manufacture. The remaining and heaviest fraction is known as "reduced crude" or "residuum." Heating and diesel oils are generally derived from the gas-oil fraction, lubricating oils from both the gas-oil and reduced-crude fractions, and fuel oils, waxes, and asphalts from the reduced crude. The proportions in which the different fractions occur vary with origin, some crude oils being rich in gasoline components, others in kerosene, and still others in lubricating oils and waxes. For physical characteristics of representative crude oils, *see* Table.

B. Chemical Characteristics

Chemically, the major components of crude petroleum are hydrocarbons, compounds of carbon and hydrogen, combined in molecules of different sizes and arrangements. Small molecules (one to four carbon atoms) constitute the gases; larger molecules (from four to about ten carbon atoms) constitute gasoline; still larger molecules (up to 50 atoms) make up the light fuels and lubricating oils, and gigantic molecules (up to several hundred carbon atoms) constitute the heavy fuels, waxes, and asphalts. Accompanying the hydrocarbon gases are appreciable amounts (up to 15% each) of nitrogen, carbon dioxide, and hydrogen sulfide, as well as smaller amounts of helium and a few other gases. In the liquid hydrocarbons there are usually found traces of oxygen, sulfur, and nitrogen, either as elements or combined with the hydrocarbon molecules.

The carbon atoms in the hydrocarbon molecules may be linked in two different ways, forming either a ring or a chain. Moreover, each of the carbon atoms may have either a full or only a partial complement of hydrogen atoms, forming saturated and unsaturated molecules, respectively. Saturated ring hydrocarbon molecules, whose chemical formula is C_nH_{2n} (where C and H stand for carbon and hydrogen atoms and n is any positive integer) are called naphthenes. Naphthenes are generally unreactive, for they can combine with other materials only by substituting for one or more of their hydrogen atoms. Saturated chain hydrocarbon molecules (chemical formula, $C_nH_{2n} + 2$) are called paraffins and are equally unreactive. Unsaturated ring hydrocarbons are called aromatics, and unsaturated chain hydrocarbons (chemical formula, C_nH_{2n}) are called olefins. Both classes of unsaturated hydrocarbons are able to combine directly with other materials without having to displace any hydrogen atoms, and consequently are very reactive. Several refining processes have been developed to increase the yield of unsaturated hydrocarbons boiling in the gasoline range. Both ring and chain hydrocarbon molecules can have appendages or "radicals," containing usually carbon and hydrogen atoms but occasionally sulfur, oxygen, or nitrogen. Most prevalent are the methyl (CH_3), ethyl (C_2H_5), and propyl (C_3H_7) radicals. Substances whose molecules have the same number of atoms of each element but different internal structures are known as isomers; although they share the same chemical formulas their chemical and physical properties differ. The chemical composition and boiling range of crude petroleum varies with the source of origin, as shown in the Table (*see* also HYDROCARBON).

II. TECHNOLOGY

A. Production

1. Exploration.—The physical and chemical characteristics of a crude oil, together with the location and extent of the deposit, largely determine its value as a raw material. Exploration is most intense in those areas already yielding or showing evidence of yielding large volumes of high-quality petroleum.

Petroleum lies hidden under the earth. No physical or chemical property of petroleum has been found which enables it to be detected from the surface. Thus the exploratory techniques, geological, geophysical, and geochemical, that have been developed do not yield perfectly accurate forecasts of discovery; at best they give the geologist only an indication of how good his chances are. Only by drilling will he learn if oil actually exists in a given location.

The modern oil industry began about 1859. In its first half-century, exploration consisted in locating indications of oil on the surface of the earth. Wells were then drilled on or near the site of the seepage. Thus the oil fields of Pennsylvania, the Caucasus, Rumania, Iran, Burma, and Sumatra were opened up.

The profits from oil discoveries were so attractive that wells were often drilled by "wildcatters" in the absence of any favourable geological indications. Wildcat discoveries opened many oil fields, those in Ohio, Illinois, and Kansas in the United States being only a few. Most wildcat wells benefit from local or regional geological knowledge and from accumulated experience in the area. However, in the decade of the 1950s only about one in every eight wildcat wells was successful.

Scientific exploration developed at the beginning of the 20th

century when geologists began to map land features as indicators of favourable places to drill. Particularly revealing were outcroppings which gave evidence of alternating layers of porous and impermeable sedimentary rock. Porous rock, typically a sandstone, limestone, or dolomite, acts as a reservoir for any petroleum present. In porous rock petroleum can move, under a pressure differential, through the interstices and cracks to a point of withdrawal; *i.e.,* to the bottom of a well. Impermeable rock, typically clay or shale, acts as a trap, preventing the migration of petroleum from the reservoir. The probability of discovering useful amounts of oil is highest when the alternating strata are uplifted into domes or anticlines, for under the domes the impermeable or "cap" rock entraps all the petroleum that migrates from more distant reservoirs. The thicker the reservoir rock—the range is from a few feet to several hundred—the greater is the potential yield of oil; the more permeable the rock, the greater is the fraction of the oil trapped in the reservoir that can be recovered. (*See* PETROLOGY.)

Within a decade after 1900 most of the areas in the United States whose structures seemed promising from the surface had been drilled to the greatest depths possible with existing equipment and methods, and substantial discoveries had been made in Texas, California, Louisiana, and Oklahoma. Oil was also found in Canada, Poland, Germany, India, Peru, Mexico, and Trinidad.

In the early 1920s the era of subsurface exploration for oil began. For areas where strata were not exposed sufficiently to permit surface mapping of underground characteristics, new geological and geophysical techniques were developed.

By the 1960s the geophysical techniques—gravity, magnetic, and seismic—were being used in the search for oil. (*See* GEOPHYSICAL PROSPECTING.) The gravity technique employs the gravimeter, a sensitive instrument which can measure variations in gravitational force. These variations are produced by, among other things, varying density of the rock beneath the surface. Dense rocks, when located close to the surface, increase the pull of gravity while sedimentary rocks, being light, do not. After many gravity readings have been taken over an area, lines of equal gravitational force can be drawn on a map. From the map the slant of the strata and certain other anomalies can be detected, although precise interpretation of the subsurface character of the rocks is impossible.

The magnetic technique, like the gravity, yields on a map of the terrain lines of equal force, in this case of equal magnetic flux. Variations in the earth's magnetic field are caused by the existence of magnetic bodies under the earth. Igneous rock generally contains more magnetite and thus gives higher readings on a magnetometer. Again, as in gravity maps, interpretation is imprecise, although it does help to reveal the depth at which igneous rock replaces sedimentary. The magnetic method can be applied over land or water, and the readings can even be recorded on an instrument towed behind an airplane.

More expensive, more laborious, but more accurate are seismic methods of exploration. Seismic methods are based on the fact that shock waves traveling downward from the surface of the earth are reflected or refracted by the interfaces between the strata. Returning to the surface, the shock waves are observed by recording devices called geophones, located at different points on lines radiating from the hole in which an explosive charge is detonated. At the instant of the explosion each geophone records the shock wave traveling along the surface of the ground. At later instants the geophones receive successive signals reflected to the surface from the interfaces, or "horizons," the intervals being longer the farther the geophones are from the explosion and the slower the shock waves travel in the rock layers. All the signals received by the geophones are amplified and traced on long strips of moving film, giving a photographic record by which geophysicists interpret the depth and angle of inclination of the various strata.

According to the principle of refraction, shock waves striking a horizon at a slight angle will be contained and travel along the bed. If the rock bed is particularly dense the waves will not be damped completely and can be observed several miles from the point of explosion.

Reflection is the preferred technique in seismic exploration. It requires smaller explosive charges and less distant geophone installations, for shock waves inclined at a great angle to the strata are reflected or bounced back to the surface closer to the shot point. Both permeable and dense media will reflect shock waves, thereby yielding information about intermediate horizons.

Geochemical methods of analysis are used in an attempt to discover the presence of hydrocarbons in the soil or in air trapped in the soil. Although simple to apply, these techniques are not useful where overlying strata are extremely dense.

With information about underlying strata gained from gravity, magnetic, and seismic surveys, geologists can make inferences about the potential yield of oil from an area. But the interpretation of geophysical and geochemical data falls short of being an exact science, and the only way to tell whether or not oil lies below the surface is to drill for it.

Some wells are drilled primarily to yield oil, others primarily to yield information. Since the latter type are much simpler and cheaper, requiring less apparatus, power, and time, they are frequently carried out in advance of production drilling. Both test and producing wells yield actual samples of the underground strata. As the drill penetrates the earth the rock cuttings, flushed to the surface, can be analyzed. Geological analysis of the cuttings indicates the chemical and physical properties of the rock; continuing analyses over the course of the drilling provide a record known as a log. Periodically a core sample (a rod of solid rock cut out by a special hollow drill) is taken for a more detailed analysis in a field laboratory. There paleontologists examine embedded fossils, hoping to find those normally associated with the presence of hydrocarbons. Also, if present in quantity, crude oil can be detected by examining samples under ultraviolet light.

After a well has been drilled it may be desirable to obtain more information than is given by the geological log. Electric logs, radioactivity logs, temperature logs, and caliper logs all provide such data. The electric log records the variations in electrical resistivity attributable to different rock formations and the minute electric currents that circulate between permeable and impermeable beds. The radioactivity log, temperature log, and caliper log record, throughout the depth of the well, variations in radioactive emission, temperature, and borehole diameter, respectively. While these logs are of little use in themselves the variations can be correlated with the properties of the rock through which the well passes. For example, a decrease in resistivity would be an indication of the presence of a liquid-bearing stratum.

2. Drilling.—Drilling for oil is a complex activity. Two methods, cable-tool and rotary, are available, although the former is no longer much used for the deep holes required in most modern oil fields. Cable-tool drilling consists in breaking up the rock by percussion. A string of tools, comprising a heavy drill bit, drill stem, and a set of links called "jars," all suspended from a cable, is lifted a few feet and then dropped onto the bottom of the hole. A slurry of mud and water, added to the hole, holds the rock chips in suspension, and the string of tools must be removed periodically so that the slurry and accumulated chips may be bailed out.

CREW USING PIPE CLAMPS TO UNSCREW SECTIONS OF DRILL PIPE AS IT IS REMOVED FROM HOLE TO REPLACE DRILLING BIT

The time required for this operation, which is not necessary with rotary drilling, plus the slower rate of drill penetration, has made the cable-tool method practically obsolete for deep holes and it is now used mainly for shallower water wells.

The rotary drilling method requires thousands of feet of drill pipe and well casing, a derrick, a power source or prime mover, drill bits, drilling muds and chemicals, and a team of several men labouring for many weeks—all necessitating considerable capital investment. The drill bit is attached to a string of drill pipe, to the top of which is connected a tube of square cross-section called the kelly; the kelly passes through a square hole in a power-driven turntable, rotating the drill string and bit, and lengths of drill pipe are added just below the kelly as the bit progresses downward. Cuttings are removed by a circulating mud slurry which is pumped through a swivel at the top of the kelly, down the drill pipe, and out through holes in the bit, whence it carries the cuttings up the annular space around the drill pipe and into a settling pit on the surface. The drilling mud, by hydrostatic pressure, also helps prevent the collapse of unstable strata into the hole and the intrusion of water from water-bearing strata that may be encountered; however, where the hydrostatic pressure of the mud column is not sufficient, steel well casing, slightly smaller in diameter than the hole, is inserted to seal off the undesirable formations.

Drilling muds consist of a mixture of clay, usually bentonite, and water, with special chemicals added to compensate for varying composition of the water and the formation being drilled. The mud, in addition to carrying rock cuttings to the surface, also lubricates and cools the drill bit.

Power to rotate the drill string, raise and lower the drill string and casing, and operate the mud pump and auxiliary equipment is provided by the prime mover. Formerly steam engines were used, but most modern drilling rigs employ diesel power. On very deep holes, where the heaviest loads are encountered, as many as eight diesel engines may be interconnected to provide the necessary power. (*See* also DRILLING MACHINERY.)

When an oil-bearing formation is reached, either of two methods may be used to prevent the incursion of unwanted water, gas, sand, etc., from other formations. A second string of casing may be inserted inside the original casing and cemented at the bottom, or cement may be pumped down between the original casing and the hole wall. The drilling mud is then removed, the cement is perforated at the level of the oil-bearing formation, and the flow of oil can commence. For wells that flow freely, as distinct from those that have to be pumped, all that is needed is a master valve assembly, called a "Christmas tree," at the well-top to control the rate of output. Drilling is finished and the well is a producer.

Drilling for oil is expensive. Wells drilled in the early 1960s in the United States descended on the average to a depth of more than 4,400 ft. (One well in Louisiana produced oil at 31,413 ft.) At an average cost of $15 per ft., an average well thus involved an expenditure of about $65,000.

Expenditure per well within the United States rose somewhat after World War II, due partly to the general postwar rise in the cost of all goods and services and partly to the cost of exploring new areas. Compensating for much of the rise in costs, however, were improvements in drilling methods and equipment: after 1945 rates of penetration were increased by nearly 50%. In undeveloped countries where work often has to be done in desert, jungle, or swamp, and where the oil explorer has to provide all the utilities at points often remote from the seaboard or main centres of population, the drilling of a single well may involve the outlay of millions of dollars.

Drilling for oil involves many risks. If oil is found it may be of very low quality and unusable, or the volume of oil discovered may be too small for commercial exploitation, or gas may be found instead of oil and there may not be any commercial outlet for it. Even in proven fields it is not certain that a new well will produce oil. Out of 16,647 field wells completed in the United States in the first half of 1960 (a typical year), 4,295 or 26% were dry. When wells are drilled in virgin territory the chance of failure increases considerably. Out of 4,708 exploratory wells drilled in the United States during the same period, 4,090 or 87% were dry. In some other oil-producing areas of the world, where reserves have not been so extensively tapped, the chance of success may be higher, but in new territory they may be much lower.

3. Offshore Drilling.—Oil may be found under water as well as under dry land, and its recovery is sufficiently profitable to encourage off-shore drilling. The first attempts were made in California, where the coastal oil fields were observed by means of subsurface well-surveying instruments directed toward the continental shelf. Wells were drilled from shore locations on a slant to the oil pools under water.

Next, drilling in lakes, bays, and shallow-water areas of the con-

OFFSHORE DRILLING PLATFORM IN THE GULF OF MEXICO

Platform is of the "crane-leg" type, resting on ten adjustable legs seated on the ocean floor; helicopter platform at left facilitates transportation between shore base and drilling rig

tinental shelf was made possible by the development of suitable equipment for drilling from barges and special foundations. Three types of drilling rigs (self-contained, with fixed platforms or mobile platforms, and derrick platforms with floating drilling tenders) are used for these operations. A floating drilling platform or drilling vessel later was evolved. It is anchored and relies on buoyancy instead of (as in the above cases) piles or legs driven into, or resting on, the sea bottom. The reservoir under Lake Maracaibo in Venezuela was the first extensive off-shore field to be developed. The Gulf of Mexico, the Caspian Sea, and the Persian Gulf also yield offshore oil in large quantities, and offshore drilling has taken place off Trinidad, Libya, Egypt, West Africa, British Borneo (now Malaysia), Japan, the Netherlands, and the United Kingdom.

4. Recovery.—The natural gas that accompanies crude oil in the ground is under compression, and it often provides sufficient energy to move the oil through the porous rock to the bottom of the well, and sometimes up the well to the surface. Similarly, water associated underground with the oil may be under pressure and thus provide some of this energy.

Properly conserved, these two natural forces can expel a large amount of the oil in the formation. Good engineering practices call for production methods which do not permit the pressure in the reservoir to be reduced below a minimum amount. Sometimes pressure can be maintained by controlling the rate of oil withdrawal, but it is often necessary to use other means. Sometimes the gas that comes to the surface with the oil is gathered and pumped back into the oil reservoir, where it helps to maintain pressure. Sometimes it goes to waste because there is no economic outlet for it, but whenever possible the gas is treated and then used for heating, power, or other purposes. In fields where a water drive exists, the injection of additional water into the reservoir provides an effective way of maintaining pressure and recovering more oil.

Under modern conservation methods, some fields are still flowing after 10 or 20 years of operation. However, pumping is necessary when insufficient gas or water pressure is present to move oil from the reservoir to the surface. This may occur in the first development of the field or after most of the original pressure has been depleted. In nearly 600,000 producing wells in operation in the United States, over 500,000 were utilizing artificial lift. A large percentage were classified as "stripper" wells; *i.e.,* wells which are pumped infrequently, yielding on an average slightly over 3 bbl. daily. (The barrel is equivalent to 42 U.S. or 35 imperial gallons.)

B. Transportation and Storage

Most of the world's crude petroleum is produced in areas remote from the main centres of demand; transporting it to the refineries and markets requires extensive, specialized facilities: pipelines, tankers, bulk barges, tank cars, tank trucks. The petroleum industry has successfully integrated these so as to provide a steady flow of crude petroleum and products from well to consumer.

Petroleum, being a fluid, is easy to transport, and very little loss of product is incurred in moving it about. It is also cheaper to transport petroleum in bulk over a long distance than to transport an equal amount of other energy sources. Thus petroleum moves in international trade, satisfying the main energy requirements of countries lacking indigenous resources.

The lowest transportation costs are obtained with pipelines. The next cheapest mode is by ocean tanker, where costs per barrel or ton have been reduced by building larger vessels. Petroleum products are also carried in smaller quantities in separate containers; *e.g.,* cylinders for liquefied petroleum gases and tins and barrels for kerosene and lubricants.

1. Pipelines.—Since pipelines are the cheapest form of transportation, they are used wherever possible. When the crude oil emerges from the well, it usually flows or is pumped through a pipeline to a central location where it merges with oil from other wells. These pipelines leading from individual wells to storage depots are called gathering lines. If the refining centre lies overland from the producing wells, the crude petroleum will be pumped to it through a pipeline. Long pipelines (up to 1,500 mi.) of wide diameter (up to 36 in.) carry large volumes (up to 400,000 bbl. per day) of crude oil from fields in Texas, Louisiana, and Oklahoma to refineries in the Midwest and on the East Coast of the United States; from the fields in Alberta to the Great Lakes; from fields in Saudi Arabia and Iraq across the desert to ports in Syria and Lebanon; and from fields in the Sahara to the Libyan and Algerian shores of the Mediterranean.

Although the pipeline is the cheapest mode of transportation, it requires a large and steady flow between two fixed points in order to justify the large capital expenditure involved. The major items of cost are the pipe itself, its laying over the terrain (requiring usually that a trench be made, and the pipe be coated against corrosion), and the pumping stations (situated from roughly 50 to 200 mi. apart, and equipped with large diesel engines which provide the pressure differential necessary to overcome friction and differences in elevation). The cost in the U.S. of a 30-in. diameter pipeline, 1,000 mi. long, carrying 400,000 bbl. of crude oil per day would be: capital cost of the pipeline about $150,000,000, of which the cost of the pipe represents 50%; pipe laying, 30%; pumping stations, 10%; and cost of right-of-way, surveying, etc., 10%. The economics of pipeline construction and operation is such that the largest diameter pipelines are the cheapest per barrel of product transported. Consequently, any two terminals are connected by single lines of large diameter rather than two or more parallel small lines.

Where large volumes are involved, the products of the refinery are also shipped to consuming centres by pipelines. Several grades of oil (gasolines, furnace oil, diesel oil, etc.) may even be shipped in the same line at the same time, in sequences or "slugs" of several tens or hundreds of thousands of barrels each. There is a slight amount of mixing between one product and the next, but this is small relative to the total volume shipped. Products pipelines exist primarily in areas of high consumption, *i.e.,* the Northeast and North Central United States and Western Europe.

2. Other Means of Transport.—*Tankers.*—Where a large body of water lies between the oil fields and the refinery, or the refinery and consumers, the preferred mode of transport is by tanker. Tankers are at a disadvantage compared with pipelines because their return journeys must be made empty, whereas the pipeline can always be full. The advantages of tankers, however, are that their routes are flexible and their ports of origin and destination variable. Tankers were introduced early in the history of the oil industry, being developed originally in the 1880s to carry crude oil and kerosene from the United States, then the main oil producer, to Europe, and from Russia to the Far East.

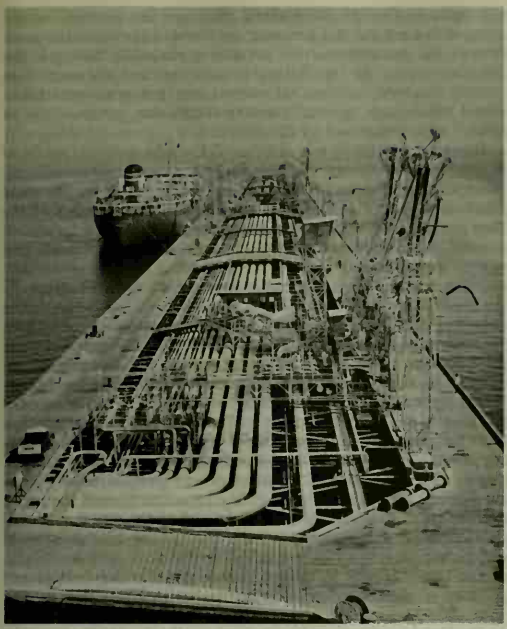
Oil tankers are built in all sizes from several hundred tons to over 100,000 tons, the former used for coastal shipments and the latter for ocean voyages. Like crude-oil pipelines, the largest tankers tend to be the most economical when used at full capacity. Japanese shipyards built, in 1962, a tanker of approximately 130,000 deadweight tons, and vessels of over 150,000 were contemplated. The building of large tankers is limited by the depth of the Suez Canal and the limited number of ports that can accommodate such vessels.

A number of countries have taken measures to promote the creation or growth of their own ocean tanker fleets, but more than half the world fleet is owned by tramp operators and more than one-third by oil companies. Some owners register their vessels in those countries which offer the greatest legal and economic advantages. Liberia and Panama are particularly attractive, approximately 20% of the world's tonnage being registered under these "flags of convenience."

Barges.—Since navigation on the ocean is easier than on confined bodies of water, tankers move faster than barges. The latter, which are used primarily for shipping finished products by inland waterways, average approximately half the speed of tankers.

Tank Cars.—Railroad tank cars, although capable of traveling at high speed, where complete direct trainloads can be dispatched, are used primarily for small or intermittent shipments.

Tank Trucks.—Road transport of petroleum by the mid-20th century showed the greatest relative increase, and by the begin-



BY COURTESY OF THE KUWAIT OIL COMPANY LIMITED; PHOTOGRAPH, B. A. CARDEW

PIER AT MINA AL AHMADI, KUWAIT, EQUIPPED WITH SPECIAL FACILITIES FOR QUICK LOADING OF PETROLEUM INTO TANKERS

ning of the 1960s there were approximately 110,000 trucks in the oil industry's service in the United States alone. Sixty per cent of these were assigned to the delivery of fuel oil, both to residences and to factories.

3. Storage.—Because the flows of crude petroleum and refined products cannot be exactly synchronized with market demand, specialized storage is provided between successive stages of production and distribution. The earth itself acts as a reservoir for crude petroleum. Disused mines and natural caverns are sometimes used to store oil or gas. Constructed storage is provided at terminals where gathering lines bring crude petroleum which continues on its journey by a cross-country line, tanker, tank car, or truck. At its destination the crude petroleum goes into storage tanks, some as large as 100,000 bbl., from which it is drawn for refining. Similarly, each refinery will have tankage devoted to the storage of products. Petroleum products are also stored at distribution depots, service stations, and retailers' premises in or near centres of population, above ground in "tank farms" and below ground in buried tanks.

C. Refining

1. Purpose and Location of Refineries.—The function of petroleum refining is to divide crude petroleum into its various boiling ranges, called "fractions," and to reconstitute and refine these fractions into different products. Where possible, refining processes are adapted to meet the demands of consumers; at the end of the 19th century, when kerosene was the major product, refiners in the United States were processing crude oil which yielded 60% to 70% kerosene, but there was little demand for gasoline or the other products. By mid-20th century, gasoline was the product in greatest demand in the United States and refiners obtained 50% yield of it. Changes in demand may bring about an adjustment in operations or a development of new processes, and even during one year a refiner's processing scheme may change: when, during the winter months in cold climates, the demand for furnace oil is high, its output will be increased to the maximum. When the demand for gasoline is high in the summer, its output will be increased. Thus, the refiner is able to meet seasonal or regional demands and reduce storage and transportation costs. Many countries find it necessary, however, to import petroleum products which local refineries cannot produce economically or to export products for which there is no home market.

A characteristic of petroleum refining has been the great technological progress. The amount of resources necessary to refine a barrel of crude oil, in terms of capital, labour, fuel, and time, was far less in the 1960s than in the 1900s or even after World War I. A rough comparison of the overall productivity at different dates in the U.S. refining industry shows the changes to be substantial. In the United States in 1919, the first year for which such figures are available, when 362,000,000 bbl. of crude oil were refined, the total number of refinery workers was approximately 59,000. Each worker on the average processed 6,100 bbl. of crude oil. In 1958, when the amount of crude oil refined was 2,776,000,000 bbl., the labour force engaged in refining had increased only to 192,000. In 1958, therefore, each worker engaged in petroleum refining processed 14,500 bbl. The increase in productivity over the 40 years, largely attributable to investment in new plant and equipment, was nearly two and a half times.

In these 40 years also the output of gasoline, the most valuable of the refineries' products, rose from 94,000,000 bbl. to 1,410,000,000 bbl. In 1919, refiners' output of gasoline represented 25% of the input of crude oil, whereas in 1958, largely because of the evolution of new processing methods, they were able to produce 44.9% gasoline of much higher quality.

Refineries are located either at the sources of crude oil, at points of transshipment, or near the product markets. In the early days of the oil industry, when kerosene, lubricating oil, and fuel oil were the only products of any value, and the volume of trade in each market was relatively small, location at the source of supply of crude oil economized on transportation costs and permitted the concentration of investment. Refineries distant from the oil fields had to transport all of the crude oil, not merely that portion represented by the marketable products. With the advent of the automobile and other developments in demand, nearly all of the products from crude oil became profitable, and what had been a disadvantage to refineries located near consumer markets changed to an advantage. Because it is cheaper to transport crude petroleum than it is to transport the smaller volumes of its individual products, market-oriented refineries have a cost advantage. Moreover, the market-oriented refinery can draw its crude oil from alternative sources, whereas a production-oriented refinery depends upon the output of a single field or area. The trend toward market-oriented refineries was particularly evident in the post-World War II era, with many new refineries being constructed all over the world.

In an oil refinery, very large volumes of petroleum are processed, yet except for small samples, taken periodically and analyzed in the control laboratory, the oil itself is never seen after it arrives at the refinery. In monitoring the performance of the equipment the operators of the refinery rely upon such indirect observations as temperature, pressure, flow rate, and liquid level. The crude oil, the semifinished products, and the final products are heated, cooled, contacted with nonorganic materials, vaporized, condensed, agitated, cracked, and polymerized continuously without human intervention.

The refinery processes can be divided into three different classes: physical separation, chemical alteration, and purification. The extent to which these three activities are carried out depends upon the pattern of demand and the characteristics of the crude oil being processed.

2. Separation.—The first class of processes, physical separation, involves distillation, carried out in distillation towers (tall, slender, cylindrical vessels fitted on the inside with a series of horizontal trays or decks). Crude petroleum, after having been pumped through the tubes of a furnace or still, where it is heated sufficiently to vaporize all but the heaviest portion, is dispelled into the distillation column from a nozzle located just above the

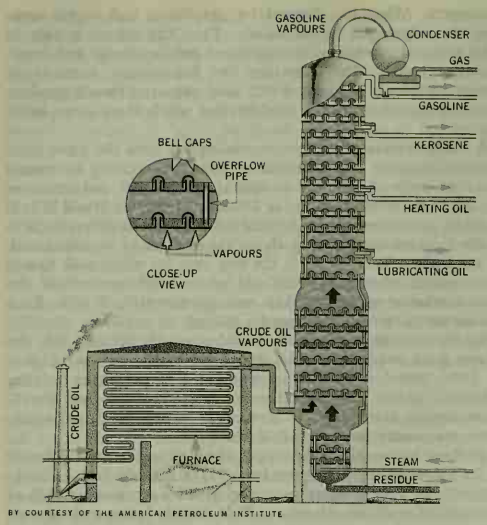


FIG. 2.—FRACTIONATING TOWER USED FOR PETROLEUM DISTILLATION

base. The vaporized portions of the crude oil rise up through the column. A temperature gradient is established throughout the tower such that the temperature is the lowest at the top and highest at the bottom. Ascending vapours condense as they rise in the tower. Condensed liquid collects on the trays whence it is withdrawn in a stream. From the top of the tower flow the gaseous vapours. Material boiling in the gasoline range is withdrawn from slightly below the top, kerosene below that, gas oil from the middle, and residuum from the bottom. Each of the streams from the distillation column then proceeds to a further processing stage.

The residuum may be redistilled in a tower operating under a near vacuum, where all but the heaviest fractions will vaporize. The refiner thereby separates residuum into light and heavy lubricating oils, and residual fuel or asphaltic material.

The second method by which proportions of crude petroleum can be separated physically into their components is by solvent extraction. Solvents are used primarily in extracting the best lubricating oil stocks from other portions of residual crude boiling in the same range. A solvent, furfural, obtained from oat hulls, is the main extractant. After extraction, the lubricants are separated from furfural by distillation.

3. Chemical Processing.—The second important class of refinery processes are those which alter the characteristics of the petroleum hydrocarbons. These chemical processes have one of three aims: to "crack" or split large hydrocarbon molecules into small ones; to polymerize or unite small hydrocarbon molecules into larger ones; or to rearrange the molecular structure.

Historically the cracking processes have been the most significant. During the 19th century cracking was used to double the yield of kerosene from crude oil. Gas oil, the raw material, was subjected to temperatures of 700°–800° F, at which point the molecules would commence to decompose.

The advent of the automobile in the early 1900s created a demand for gasoline, formerly a product of little value. The demand soon exceeded the amounts of gasoline which could be obtained merely by distilling the light fractions of crude petroleum, so that an incentive existed to obtain a greater yield of gasoline by cracking. In 1913 the first commercially successful process, named after its inventor, William M. Burton, was introduced by the Standard Oil Company (Indiana). The Burton process utilized the same temperatures that had been used in cracking for kerosene but carried out the cracking at elevated pressures, up to 75 lb. per sq.in. (psi). At atmospheric pressure, the products of decomposition are gas and kerosene; at elevated pressures the products of the cracking reaction are mainly materials boiling in the gasoline range. In the Burton process the raw materials were treated in single batches, but several new processes were introduced which made thermal cracking continuous; temperatures of 900° F were being used by the 1930s.

During the 1920s it was discovered that the gasoline produced in cracking had superior burning characteristics in automobile engines, and so what had been of advantage in increasing the yield of gasoline became also of advantage in raising the quality of the final product. With higher-quality motor gasoline the compression ratio of automobile engines could be increased and more efficient operation obtained.

The next advance was the development of catalytic cracking. Although it had long been known that some materials, known as catalysts, could increase the rate and nature of cracking without themselves being affected, it was not until 1936 that two American oil companies, Socony Mobil and Sun, adopted the process developed by a French-born engineer, Eugène Jules Houdry. Gasoline components produced by catalytic cracking were far superior to those from thermal cracking. Moreover, the yield of gasoline from a given volume of raw material was greater. Catalytic cracking units, first those following Houdry's design and later the improved versions developed by others, were rapidly installed. During World War II catalytically-cracked gasoline formed the major component of aviation fuel; after the end of the war it was used in automotive fuel, thereby raising the quality of this product still higher.

The catalysts used in catalytic cracking are mainly oxides and silicates of aluminum and magnesium, which occur naturally in such clays as bentonite and are also manufactured synthetically. In the Houdry process and its derivatives, the Houdryflow and the Thermofor Catalytic Cracking (TCC) processes, the catalyst is agglomerated into small beads. In the other major catalytic cracking process, the Fluid process, the catalyst particles are very small, forming a powder which has properties similar to those of a fluid.

Polymerizing and reforming processes have been evolved to raise the flexibility of the modern refinery and to increase the yield of gasoline. Polymerization (*q.v.*) is the reverse of cracking. Whereas cracking breaks down the heavier gas-oil or heavy fuel molecules into the lighter ones of gasoline, polymerization combines the still lighter molecules of certain gaseous by-products into molecules suitable for motor fuel. Developed in the 1930s, polymerizing processes are important adjuncts of all refineries.

The first polymerizing process introduced, called polymerization, after the reaction itself, utilized as raw materials unsaturated hydrocarbon gases, primarily propylene and butylene. Another polymerization process, alkylation, combined either of these two same raw materials with isobutane, a saturated hydrocarbon gas. Introduced a few years later than polymerization, alkylation contributed greatly to the production of aviation gasoline in World War II. Like polymerization, alkylation can increase a refinery's motor gasoline yield by approximately 5%. Both processes are similar, also, in that the polymerizing reactions are carried out in the presence of a catalyst.

The third type of chemical processing, after cracking and polymerizing, is one that alters the molecular structure of the hydrocarbon molecules. This alteration, called "reforming," is carried out in order to improve the combustion characteristics of the product. Applied primarily to low-quality gasoline stocks, usually those obtained from crude petroleum by distillation, the reforming processes can substantially improve the quality of the resulting product. Introduced in the 1930s in a process very similar to thermal cracking, reforming became more significant in 1949 when the first catalytic reforming process, "Platforming," was developed by Universal Oil Products Company. Utilizing a platinum catalyst, the Platforming process (with several derivative methods subsequently introduced by competing process development companies and the major oil companies) improves the quality of gasoline without detracting from the overall yield.

In the decades of the 1930s, 1940s, and 1950s the major force

motivating refiners, especially in the United States, was the urge to increase the quality of their motor gasoline without diminishing its yield. They were aided in this attempt not only by the development of new refining processes but also by the introduction of tetraethyl lead as an additive. In 1922 T. Midgly, Jr., and C. F. Kettering, working for General Motors, discovered a class of organic compounds which, when added to motor gasoline, would drastically reduce engine knock. Starting a few years later, tetraethyl lead, the most reactive of the class, was added commercially to gasolines in amounts up to 3 cc. per gal.

There are several measures of gasoline quality, some recording its stability, some its gum-forming tendencies, and some its burning characteristics. Perhaps the most useful single measure is the octane rating, a number on an arbitrary scale commencing at 0 (a fuel with combustion characteristics equivalent to normal heptane) and rising to above 100 (iso-octane was assigned the number 100). A fuel which is assigned the value of 90 octane therefore has combustion characteristics or "knock rating" equivalent to a fuel composed of 90% iso-octane and 10% normal heptane. Measured on this octane scale, the average quality of motor gasoline produced in the United States rose from approximately 50 in 1915 to over 90 in the 1960s. The quality of premium fuel rose even above 100 octane.

Coinciding with the rise in octane number was the rise in the compression ratio of automobiles. The combined improvement resulting from increase in gasoline quality and in compression ratios in automobile engines was most accurately reflected in engine performance. Between 1925 and 1960 automobile performance more than doubled, for regular-grade fuels from 24.0 to 53.5 ton-mi. per gal.

Tetraethyl lead was the first additive in petroleum products; many others were later developed. Additives were introduced to improve the flow of lubricating oils at both very high and very low temperatures, to reduce the oxidation of fuels (which is responsible for the formation of gum and the clogging of engine parts), to help lubricants to resist corrosion, and to act as detergents by retaining in suspension dirt and other contaminants.

4. Purification.—The third class of refinery processes includes those which purify the products. There are in crude oil many non-hydrocarbon elements, primarily sulfur, which impart undesirable properties. If left in some products these impurities would cause corrosion and unpleasant odour, and many refinery processes have been developed to neutralize or remove them: hydrogen sulfide is removed from refinery gas streams; mercaptans (complex compounds of sulfur) are removed from motor gasoline and kerosene; residual fuel may be treated to remove undesirable compounds.

5. Scale of Refinery Operations.—The average petroleum refinery combines in one large plant many different processes, and large-scale operations are needed to make refining economically feasible. It is possible to manufacture all products in one refinery, but most refineries, as far as economically possible, produce only the products needed in their local markets. In underdeveloped countries refineries are designed with relatively little catalytic cracking and reforming capacity.

Refineries process vast amounts of material daily. Running continuously for months at a time, a single distillation unit may separate as many as 100,000 bbl. per day of crude petroleum into its different fractions. A single catalytic cracking unit may crack 60,000 bbl. per day of gas oil, in addition to recirculating large amounts of partially cracked material.

Economies accompany large-scale operation. Although the amounts of fuel and catalyst, depending as they do upon the physical and chemical properties of the crude oil, do not vary appreciably with plant size, the amounts of equipment and labour do. A catalytic cracking unit of 60,000 bbl. per day will require no more men to operate it than a unit with one-tenth its capacity. The cost of labour, per unit of product, therefore is considerably less for very large units. Although not as dramatic an example as labour costs, capital gives evidence of the same economies of scale. A 100,000-bbl.-per-day refinery, although it processes ten times as much raw material as a 10,000-bbl.-per-day unit, would cost only about eight times as much to construct. Economies of scale thus encourage the construction of large refineries, and it is usually the size of the market rather than limitations on the ability to construct and operate large pieces of equipment that sets the limit to refinery capacity.

6. Petrochemicals.—A flourishing field for the refiner is petrochemicals; *i.e.*, those industrial products whose raw materials are derived from petroleum, and particularly from refinery gases. The alternative uses of these gases are either as fuel (in the case of ethane, ethylene, and propane) or as raw materials for aviation and motor gasoline (propylene and butylene).

The major use of petrochemicals is in plastics (*q.v.*), particularly polyethylene, polypropylene, polystyrene, and alkyd, vinyl, and phenolic resins. It was expected that by 1970 plastics would consume half of the total hydrocarbon raw materials available to the petrochemical industry. Next in importance are man-made fibres such as nylon, dacron, and acetate rayon; synthetic rubbers such as Buna-S, Buna-N, butyl rubber, and neoprene; nitrogen fertilizers; detergents; protective coatings; and solvents. (*See* also PETROCHEMICALS.)

D. MARKETING

The marketing branch of the oil industry distributes the products from each refinery to customers with differing needs.

The physical nature of the product influences the manner in which it is distributed. The majority of the petroleum products are liquids, stable under most conditions, capable of being contained in simply constructed tanks and of being pumped from one location to another. The petroleum products which offer greater problems of handling are those which fall at either end of the boiling range: gases, greases, heavy fuels, waxes, and asphalts. Liquefied petroleum gas (LPG) has to be stored and moved under pressure and is normally distributed to the consumer in small cylinders. Greases and some of the specialized lubricating oils are handled in barrels. Since the cylinders and some of the barrels are reused, the distributor has to provide for the return, cleaning, and testing of the containers. Heavy fuels and asphalts, because they congeal at normal temperatures, must often be stored and distributed in heated or insulated containers.

Petroleum distributors frequently separate industrial from consumer products. Industrial products are sold in large volumes to a few customers, while consumer products are sold in small volumes to a great number of customers and call for an extensive consumer marketing organization, *e.g.*, the gasoline service stations.

Where service stations are located within several miles of a refinery, they may be supplied directly via the refinery's tank cars or tank trucks. If they are more distant, they will be supplied by an intervening agent who buys wholesale from the refinery and distributes locally to service stations, sometimes maintaining his own intermediate storage facilities. Often the agent will also carry furnace and fuel oil, which he delivers to homes and industrial customers.

III. DEMAND AND SUPPLY

A. Sources of Crude Petroleum

Although the products of petroleum are consumed everywhere, crude petroleum is produced in relatively few places and often in areas of desert, jungle, or swamp. In 1963, a typical year, four-fifths of the total production of crude petroleum occurred in seven countries: the United States, U.S.S.R., Venezuela, Kuwait, Saudi Arabia, Iran, and Iraq.

Following World War II a dozen countries were added to the list of oil-producing countries, and on the continent of Africa, hitherto regarded as unpromising, large reserves were found in the Sahara and Libya, and smaller reserves in Nigeria, Angola, and Gabon. After costly decades of exploration in Australia oil in commercial quantities was found in Queensland in 1962. For reasons of national policy, new knowledge, new appraisal of prospects, and hopes of bigger rewards, oil may be sought in areas hitherto unexplored, but such a search is always expensive and speculative.

MAJOR PETROLEUM-PRODUCING AREAS OF THE WESTERN HEMISPHERE

Historically the world price for crude petroleum has been based upon the price, at the well, of oil from the company with the largest surplus production in the exporting area. During the 19th century and the first decade of the 20th, when the United States was the dominant producer, the base price was the price of first Pennsylvania and then Texas, crude oil. Crude oil prices elsewhere were calculated by adding to or subtracting from the U.S. price the difference in transport cost between the two sources and the market in which they were competing. When, in the 1920s, Venezuelan crude oil began to enter European markets in quantity, its price was determined on the basis of prices then existing along the U.S. Gulf Coast. Middle Eastern crude oil, when it first appeared in the Eastern Mediterranean, was priced according to the price in the Gulf of Mexico, again with allowance for the differential in freight rates between the Gulf of Mexico and the Eastern Mediterranean, on the one hand, and the Persian Gulf and the Eastern Mediterranean, on the other. After World War II, when Middle Eastern crude oil became plentiful, it met a large part of the new demand in the rapidly expanding markets in Western Europe, and, in the late 1940s, it began to reach the East Coast of the United States and Canada. By 1958 the United States was importing over 80,000,000 tons of oil a year (1,600,000 bbl. per day). Of this, 56% was crude oil and the rest petroleum products, and of these imported products nearly 70% was residual fuel oil from Venezuela which could not be provided economically from U.S. crude oils. In order to check these crude oil imports, the United States imposed import quotas, after three years of voluntary limitation by importers. The quotas made it possible for the United States oil industry to pursue the search for oil at home notwithstanding its relatively high costs and the increasing effort needed to find new oil in the country. Middle Eastern crude oil, in the limited amounts that were permitted to enter the United States market in the early 1960s, enjoyed a cost advantage over many U.S. crude oils.

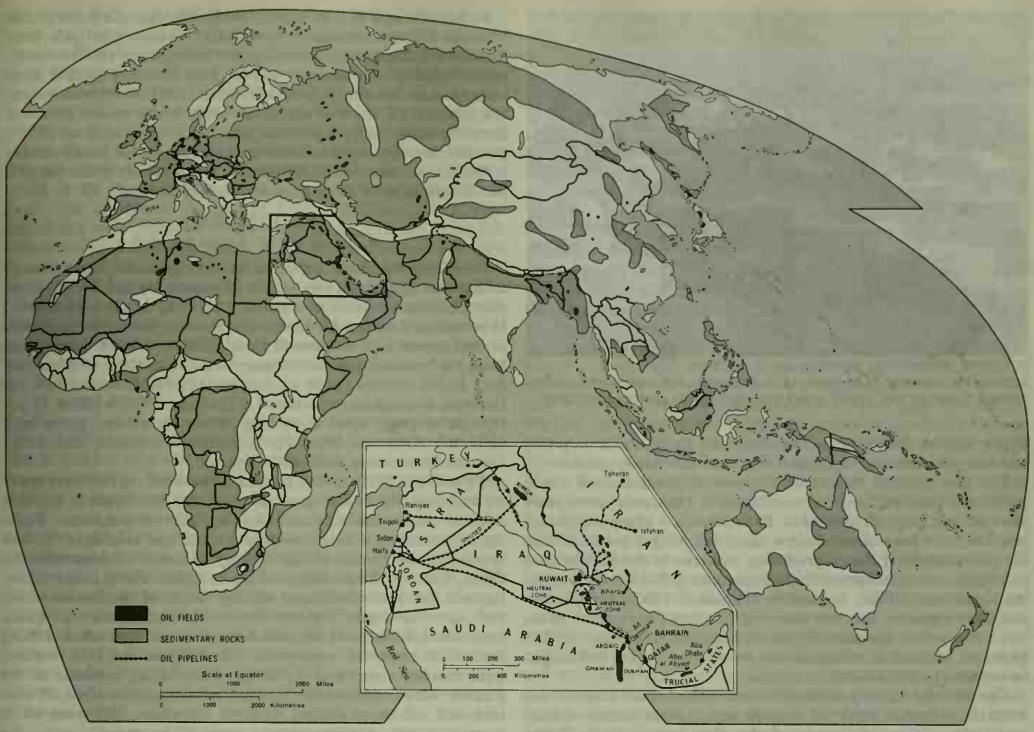
The Middle East had in the mid-1960s the largest oil accumulations, with the highest yields per well, and it was to be expected that Middle East crude oil would continue to enjoy a cost advantage over oil from other sources despite the distance it had to travel to its main markets, a handicap which was reduced by advances in tanker transport. High fiscal charges by the producing countries might, however, reduce the margin of advantage.

The total volume of oil that lies below the land and sea surfaces of the earth is unknown. The oil industry has, however, evolved the concept of "proved reserves," this being the volume of oil known to exist that can be economically recovered at current prices and by current methods. The world's proved reserves, excluding those of the Communist countries, were at the beginning of 1963 approximately 300,000,000,000 bbl. (40,000,000,000 tons); *i.e.*, equivalent to 37 years' production at the current level of demand. Demand was expected to double by the 1980s and, by the year 2000, to have reached three times the 1962 level.

B. Consumption of Products

The amounts of petroleum products that are consumed and the prices at which consumers purchase them depend in part on the original price of crude oil plus the costs of transporting, refining, and marketing; in part upon the consumers' needs; and to a considerable extent upon the level of import, sales, and other taxes (notably on motor fuels) that are levied in nearly all countries.

Industrialization following World War II was rapid, and with it the demand for fuel increased. Since the output of petroleum can be expanded more rapidly than that of other fuels, its growth was particularly impressive, although world demand for petroleum products rose virtually without interruption since the industry's earliest days. From the end of World War II up to the early 1960s, the average annual increase was about 7%, but this



SOURCES OF CRUDE PETROLEUM IN THE EASTERN HEMISPHERE

rate of growth was expected to decrease, because there would be less scope for conversion to oil from other fuels; because the demand for motor fuels in highly developed countries would not grow as rapidly as previously; and because, in some countries, natural gas was already taking the place of petroleum as a source of petrochemical products.

Four important features of the oil industry are: the wide range in the types and qualities of crude oil and the new sources which appear from time to time; the variations in the demand for the various major petroleum products; the fact that, excepting the U.S.S.R., all major oil-consuming countries are large importers of oil; and the large volume of oil that moves in international trade.

The composition of total market demand in a district, country, or region is a crucial factor in determining the demand for, and the flow of trade in, the various types of crude oil, and in determining the cost of refining operations. Two extreme instances of contrasts in the character of market demand were offered by the United States and India in the early 1960s. In the United States gasoline accounted for about half the country's total demand for petroleum products but in India only for one-sixth. In the United States the demand for kerosene was relatively insignificant (less than 5%) but in India kerosene was the dominant product and represented about 30% of total demand. Fuel oil accounted for half of Japan's oil consumption but only for a seventh of that of Australia. Though residual fuel oil accounted for only one-sixth of the total oil needs of the United States, it would not be economically feasible to provide from within the country all the fuel oil it required, hence the large imports of residual fuel oil from Venezuela into the Eastern U.S.

The changing rates of demand for the various petroleum products were exemplified by the Federal Republic of Germany, where in 1963 the demand for fuel oils had risen fivefold within five years, whereas the country's total demand for all petroleum products had risen at only half this rate. In the United Kingdom the demand for gas and diesel oils had nearly doubled in five years but that for gasoline had risen to only half that extent.

Modern oil refining techniques afford considerable latitude in matching refinery output to market demands, but there are technical limits as well as limiting factors of cost. In practice, the surplus or deficiency can often be most economically disposed of, or made good, by exports and imports. This has helped to bring about the international character of the industry and the worldwide integration of operations within the large oil groups. The remarkable growth in the number of oil refineries (which now exist in most countries of the world), and the imbalance between their output and local market demand, intensified the international movements of oil. Thus, to supply Western Europe with the 235,000,000 tons of petroleum products needed in 1962 for its inland requirements and ships' bunkers, it was necessary to move crude oil and petroleum products amounting to nearly 300,000,000 tons into and from Western Europe and between Western European countries.

A striking development was the increased demand for subsidiary petroleum products; *e.g.*, petrochemicals, including synthetic rubber and fertilizers, liquid gas, bitumen, wax, etc., and in some countries feedstock to gas works for the production of fuel gas.

C. Conservation and Output Control

Once a well has been drilled and oil discovered in commercial quantities, a producer has a great incentive to bring his production to a maximum. But if in times of plentiful supply all producers were to follow this course of action, crude oil output would rise greatly, leading to a drop in price. Similarly, if the natural pressure in a reservoir drops too fast owing to an excessive rate of production, the total volume of oil that can be economically with-

PETROLEUM STORAGE TANK FARM AT A BAYTOWN, TEX., REFINERY; BUTYL RUBBER PLANT IN THE UPPER RIGHT UTILIZES PETROLEUM BY-PRODUCTS

drawn will be diminished. Therefore, the stabilization of prices and the conservation of natural resources are closely related.

The first attempt to restrict the rate of production of crude petroleum was made in the United States in 1866, only seven years after oil had been discovered in Pennsylvania. Many restriction schemes have been devised since then, including a proposal that the governments of the oil-producing countries in the Middle East and Venezuela, members of the Organization of Petroleum Exporting Countries (OPEC, formed in September 1960), should control their output. This was intended to affect prices, since effective conservation was already practised in those countries. OPEC, however, declined to entertain any restriction scheme but sought to sustain the price level.

The need for a policy of conservation in the United States arises from the nature of crude oil deposits and the legal status of mineral rights. The U.S. is one of the very few countries in the world where the property in mineral rights belongs to the surface owner. In most of the rest of the world it belongs to the state, which grants operating rights to licensees or concessionaires and collects revenues for the benefit of the community; invariably there is only one or relatively few operators in an oil field and conservation can easily be agreed upon or imposed. With the best conservation procedures (which, however, may be costly) it is possible to recover 60%, 70%, or even more of the oil lying under the ground; with unrestrained production the fraction recovered may only be 20% or 25%. Frequently, an oil field in the United States and elsewhere will be operated as a single unit, a procedure known as "unitization." Each producer withdraws oil at a rate compatible with the interests of other producers and with securing maximum total economic recovery from the field.

Restraints on output in the United States were enforced in 1935 with the support of the governments of the state of Texas (relating to the production of the oil within the state) and of the United States (relating to the movement of oil in interstate commerce). The rate of output is determined as follows: the U.S. Bureau of Mines estimates the demand, at existing price levels, for domestic crude petroleum for the next month. The production control agencies of the various states concerned, led by the Texas Railroad Commission, apply their state's share of the total demand to this figure to arrive at the desired rate of output for the state. This rate is compared with the maximum allowable rate, calculated on the basis of obtaining the best total recovery from all the oil reservoirs within the state. Each producer is then permitted to maintain his rate of output at the same percentage as that for the state as a whole. Thus if the state wishes to produce at one-third of its capacity, each producer will be entitled to the equivalent of ten days (out of a total of 30 days) "allowables." Small producers are frequently granted a minimum rate, below which their production will not be restricted, and there is no restriction on the number of wells that may be drilled.

In Kuwait and also in Saudi Arabia, the operating companies (Kuwait Oil and Aramco, respectively), whose principals have their own transportation, refining, and distribution facilities overseas, control all the oil areas and have no incentive to drill more wells than are necessary to withdraw the crude oil for which there is a demand. The entire output of Saudi Arabia comes from less than 200 wells. Output per well, which averages as low as 12 bbl. per day for the United States as a whole, is for Saudi Arabia 5,700 bbl. per day, but this disparity arises mainly from the prolific nature of most large fields in the Middle East. (J. L. E.)

IV. HISTORY

A. From Early Times to 1918

Petroleum has been exploited in various forms since remote times. Archaeological research in Mesopotamia and Persia shows that bitumen was used as a bonding material in place of mortar. It served as a setting for jewels and mosaics, to fasten the blades of implements and weapons in their handles, to caulk vessels and build roads, and for medicinal purposes. Herodotus (5th century B.C.) in his *History* (book vi, section 119) has described how oil, bitumen, and salt were procured in his time. The working of petroleum seepages dates from long before Herodotus, going back to before 3000 B.C. when the Sumerians, Assyrians, and Babylonians, successively, utilized bitumen.

To both the Persians and the Arabs the word *naft* denotes crude oil and light distillates, used centuries ago for lighting, cleaning silk and other textiles, in medicine, and for war purposes. Burning petroleum as a device to frighten the war elephants of their opponents contributed to the military successes of Alexander the Great, Timur (Tamerlane), and Nadir Shah. Early in the Christian era the Arabs developed various means of distillation which they introduced into Western Europe through Spain. In China there are references to oil, which was encountered when drilling for salt, in the third century A.D. As early as the 12th century, wells reached a depth of 3,000 ft. The drilling methods of the Chinese were described by Christian missionaries in the 19th century and influenced drilling methods elsewhere. Burmese oil is mentioned in the Chinese writings of the 13th century.

The petroleum of Baku was being exploited on a commercial scale, by the standards of the time, when Marco Polo traveled through northern Persia in 1271–73. The oil trade of Baku is described in his *Travels* (book i, ch. iv) and by later writers—Geoffrey Duckett of the Muscovy Company in 1574; John Cartwright, an English missionary, in 1600; and, of particular note, Jean (Sir John) Chardin and Jonas Hanway in the 18th century. Nevertheless, the modern petroleum industry dates from the mid-19th century. In Scotland about 1850 James Young discovered that oil could be distilled from cannel coal and shale and pioneered various refining processes. This led to the development of a Scottish shale oil industry which flourished until the 1920s and was only finally extinguished in 1962. However, the shale industry was always subject to the economic disadvantage that its operations had to begin with mining its raw material and then go through retorting as well as refining processes. These disadvantages were accentuated after Edwin Drake's successful well at Titusville, Pa., in Aug. 1859, from which the modern petroleum industry is usually dated.

After the completion of Drake's well, surrounding areas were immediately leased and extensive drilling took place. Crude-oil output in the United States increased from about 2,000 bbl. annually in the year of Drake's strike to nearly 3,000,000 in 1863, rising to just under 10,000,000 in 1874 (7 bbl. equals approximately 1 ton). In 1861 the first cargo of oil, contained in wooden barrels, was sent across the Atlantic to London. By the 1870s refineries, tank cars, and pipelines had become characteristic features of the industry, which was, however, highly speculative and not well organized.

Since its inception the oil industry has followed a discernible pattern. Throughout the latter part of the 19th century the United States and Russia were the two areas in which the most striking developments took place. The end of this period was characterized by the opening up of the Far East and the rise of

the Royal Dutch and the Shell companies. When World War I broke out the two major producers were the United States and Russia. Certain quantities were also being obtained from Indonesia, Rumania, and Mexico, and production had begun in Persia, but on a very small scale. Oil had been discovered in Venezuela in commercial quantities on the eve of the war. In the interwar period the Caribbean Basin and the Middle East assumed great importance as Russian oil faded from the world picture. During this period the attention of the world oil industry was concentrated on the more obviously promising areas, such as the United States, the Caribbean, the Middle East, and Indonesia. Europe and Africa were regarded with little interest. In the years following World War II the Middle East continued its rise with new discoveries of vast reserves. The United States, though continuing to be the biggest producer, consumed so much of its production that it became of less importance in the international trade picture. Companies began to roam much farther in the search for oil, and this resulted in significant discoveries in Europe, Africa, and Canada. A new factor of importance was the resurgence of the Russian oil industry.

1. United States.—John D. Rockefeller completely changed the character of the petroleum industry in the United States. On Jan. 10, 1870, the Standard Oil Company was incorporated in Ohio with $1,000,000 capitalization and Rockefeller as its president. By the early 1880s he had brought approximately 80% of the refining capacity of the nation and 90% of the pipelines within the scope of his organization, which also had a large interest in railway tank cars. Rockefeller integrated downward from refining, transportation, and marketing to crude-oil production (1886–90).

Petroleum products figured prominently as a U.S. export, with the European market absorbing the overwhelming proportion of U.S. petroleum exported. At the same time domestic consumption increased rapidly. In 1900 production in the United States had reached nearly 60,000,000 bbl. annually. Standard Oil's first overseas subsidiary, Anglo-American Oil Company, was organized in 1888, and at the turn of the century it owned the world's largest oil-carrying fleet. In 1900 the total net assets of the Standard Oil organization were listed as $205,408,449.09. In 1911, as a result of U.S. antitrust legislation, the organization was broken up into more than 30 companies. Rockefeller resigned as president of the Standard Oil Company (New Jersey), which had been incorporated in 1882 under a slightly different title and which was the holding company for the group.

Some of the companies which were once part of the original Standard Oil group have become, in addition to being major units in the United States oil industry, leading participants in international operations. Of particular prominence are Standard Oil Company (New Jersey), Socony Mobil Oil Company, and the Standard Oil Company of California. The Standard Oil Company (New Jersey), often known as "Jersey Standard" or "Esso," is the largest of the world's oil companies. The Socony Mobil Oil Company was, until 1955, known as Socony-Vacuum, which had itself come into being as a result of an amalgamation of two units from the old Standard Oil group—Standard Oil of New York (Socony) and the Vacuum Oil Company. Four other members of the former Standard Oil group have been traditionally prominent in the domestic American industry—Atlantic Refining, Ohio Oil Company, Standard Oil Company (Ohio), and Standard Oil Company (Indiana); all now also engage in overseas operations.

There are two American oil companies of particular note and with worldwide interests that have their origins outside the Standard organization. One, Texaco Inc., is the successor to the Texas Company, which was incorporated in 1902. The other, the Gulf Oil Corporation, was incorporated in 1907, but its origins may be said to go back to 1889, when W. L. Mellon began to acquire oil-producing property in western Pennsylvania.

2. Russia.—When the 20th century opened, production from the United States and Russia accounted for about 90% of the world's output. In 1901 a few square miles on the Apsheron Peninsula (Caspian Sea) produced 11,700,000 tons, thus surpassing the production of the United States, which in that year amounted to 9,500,000 tons. Since the total world output in 1901 was just over 22,900,000 tons, the rest of the world accounted for only 1,700,000 tons. The extraordinary development of the Baku fields was largely the work of the Swedish brothers Robert and Ludwig Nobel, who acquired their first productive well in the Baku area in 1874. They brought many changes. They introduced proper control of their wells; they took steps on behalf of their employees' welfare; introduced pipelines on the U.S. model; built refineries; put tank cars on the railways; and initiated revolutionary techniques in water transport. Before 1879 oil was carried in barrels. In 1877 Ludwig Nobel had an iron steamer put on the stocks in Sweden. The "Zoroaster" came into service on the Caspian between Baku and the Volga in 1879 and was the first of a fleet of such tankers. Moreover, by 1883, steamers and locomotives in the Caspian region did not burn coal or wood but petroleum. By 1883 Russian petroleum was reaching German markets; by 1888, Singapore. Later it was sold in the Far East through the Royal Dutch and Shell companies. The Russian Revolution of 1917 resulted in the seizure of foreign interests, and was followed by a sharp fall in production.

3. Far East. Royal Dutch/Shell.—Based upon the pioneer work of a Dutchman, Aeilko Jans Zijlker, who obtained a concession in northern Sumatra where he began drilling in 1884, "The Royal Dutch Company for the Working of Petroleum Wells in the Dutch East Indies" (name changed in 1949 to the Royal Dutch Petroleum Company) was incorporated at The Hague in 1890. Its success owes a great deal to two men, J. B. August Kessler and Henri Deterding; the latter joined the Company in 1896 and succeeded Kessler as its chief executive in 1900. The Royal Dutch began as a producing company and proceeded to build up a sales organization in the East. Its orientation was at first eastward, partly because of proximity and also because European markets were already taken up by U.S. and Russian oil.

The Royal Dutch came into competition both with Standard and with the Samuel brothers, British merchants having a long connection with trade in the East. In 1890 Marcus Samuel visited Russia to investigate the possibilities of marketing oil from there in bulk to the Orient. He succeeded in these negotiations as he did also in persuading the Suez Canal authorities to remove the ban against tankers passing through the canal. Standard had been denied permission some years earlier because of disasters which had befallen ships carrying oil. Improvements in design had taken place so that in the summer of 1892 the "Murex," the first of the Shell fleet of tankers, passed through the Suez Canal with kerosene from Batum to Singapore and Bangkok.

In 1896 Samuel bought oil properties in Borneo which he began to develop. In the following year he organized the "Shell" Transport and Trading Company, Ltd.; so named because seashells had been one of his earlier items of trade. In 1903 the Asiatic Petroleum Company was formed with its capitalization held in three equal parts—the Royal Dutch, the Shell, and the Rothschilds, who later disposed of their interest to the Royal Dutch/Shell group. The main function of this company was marketing. In 1907 Royal Dutch and Shell transferred their other properties to two new companies which they owned jointly on the basis of 60% Royal Dutch and 40% Shell. One company, Bataafsche Petroleum Maatschappij N.V., with its headquarters at The Hague, was the operating (production and refining) company. The other, the Anglo-Saxon Petroleum Company, had its headquarters in London. Its functions included transport and storage. In 1912 the Royal Dutch/Shell group made its entry into the United States by acquiring oil interests in California. In that year, too, the Royal Dutch/Shell incorporated the Roxana Petroleum Company of Oklahoma, which became the member through which the group's interests in Oklahoma and Texas were held. This was closely followed by its entry into Venezuela and the discovery of the Mene Grande field in 1914. Venezuela later became the largest exporting country and the second largest producer in the world.

4. Venezuela.—It is said that Venezuela first exported petroleum in 1539 when a barrel of crude oil was sent to the king of Spain. Pirates in the 16th century frequently used the

pitch of the Lake Maracaibo region for caulking their ships. In the late 1870s a small Venezuelan company drilled a few wells about 60 ft. deep at a seepage site in order to obtain crude for local use as an illuminant. It was the Caribbean Petroleum Company, a subsidiary of Royal Dutch/Shell, which in 1914 discovered the first field (Mene Grande) of real commercial importance. In 1917 another Royal Dutch/Shell subsidiary associate, Venezuelan Oil Concessions, Ltd., opened up the La Rosa field on the east side of Lake Maracaibo. In 1922 one of its wells flowed wild for nine days at the rate of 100,000 bbl. per day. This called attention to Venezuela as an oil country and encouraged intensive and successful exploration by various oil companies.

5. Rumania.—In Rumania the existence of oil had been known for centuries. In 1857 hand-dug wells produced 275 tons. Operations on a larger scale followed the introduction of modern drilling techniques and the infusion of foreign capital, chiefly German through the Deutsche Bank. In 1903 Rumanian production reached 412,000 tons, rising to 1,848,000 tons in 1913. During World War I the Entente authorities decided (1916) upon the destruction of as much of the oil plant in Rumania as possible. The main Allied investments affected were those of the Royal Dutch/Shell group and certain French interests. In 1917 production fell to 518,460 tons, but rose substantially in the following year to 1,222,582 tons. As a result of the German defeat its properties in Rumania were sequestered and handed over to the Allies.

6. Persia and the Middle East.—Before the outbreak of World War I the oil industry was established in Persia, the first of the great producing countries of the Middle East. It was upon the work of the French archaeologist Jacques de Morgan that William Knox D'Arcy (a wealthy Englishman who had made a fortune goldmining in Australia) based his belief in Persian petroleum as a paying commercial proposition, in spite of the failure of others before him to achieve any success. Early in 1901 D'Arcy's representative in Teheran entered into negotiations with the Persian government. Signed on May 28, 1901, D'Arcy was granted a concession for 60 years. It covered the whole of Persia except for the five northern provinces adjacent to Russia.

D'Arcy's first exploratory drilling was at Chiah Surkh in the west, where there were surface seepages of oil, but no production of commercial significance was proved by 1904, after which drilling operations were moved to southwest Persia. Oil was struck there on May 26, 1908. When further wells drilled nearby proved successful, it became evident that a major oil field had been discovered. On April 14, 1909, the Anglo-Persian Oil Company, Ltd. (APOC), was incorporated with Lord Strathcona as its first chairman. The oil field was connected by a pipeline 135 mi. long with a refinery on Abadan Island which came into operation in 1913. The financial resources of the APOC in its early days were slender, but in May 1914 the British Admiralty, of which Winston Churchill was first lord, signed a long-term contract with the company for the supply of fuel oil to the Royal Navy. Simultaneously, the British government invested £2,000,000 in the company, followed by a further £3,000,000 in 1919. Thus the company had acquired a long-term customer and finance for expansion. As a result of its investment the British government became the owner of just over 50% of the company's equity, as it has remained to the present. At the time of the original investment the government gave an assurance that it would not interfere in the ordinary commercial operations of the company.

D'Arcy had endeavoured since 1901 to obtain an oil concession in Mesopotamia (now Iraq), then part of the Ottoman Empire. His representative in Constantinople came near to success but failed to achieve it. The Anglo-Persian Oil Company, as D'Arcy's successor, persevered with negotiations against keen competition from other groups. In October 1912 the Turkish Petroleum Company was registered in London as the new name of the African and Eastern Concessions, Ltd., which had been incorporated in January 1911. This brought together the interests of the National Bank of Turkey (formed in 1910), C. S. Gulbenkian (then adviser to the sultan), the Deutsche Bank, and the Shell group. The Anglo-Persian Oil Company was not represented in this combination, but in 1914 the firm joined in a reconstituted Turkish Petroleum Company, taking half the share capital of £160,000. The other participants were the Deutsche Bank with £40,000; Anglo-Saxon (Shell) with £40,000; and Gulbenkian with 5% to be provided equally from shares of Anglo-Persian and Anglo-Saxon. On June 20, 1914, the Turkish government agreed to lease the petroleum deposits "discovered or to be discovered" in the *vilayets* of Baghdad and Mosul to the Turkish Petroleum Company. The outbreak of World War I delayed the development of the country's oil resources.

7. The Effects of World War I.—In World War I, changes already under way—such as the use of oil for fuel in ships—were greatly speeded. The diesel-engined submarine was first used on a large scale, and the gasoline-engined airplane emerged as a new weapon. After the war the automobile gained rapidly in popularity, providing a new peacetime demand for petroleum products. The emergence of petroleum as a vital war material, together with the new and widespread uses for petroleum products, made the possession of adequate supplies a matter of national interest. The U.S. government, for example, encouraged companies to undertake operations abroad.

B. From 1919 to 1939

1. Venezuela.—After World War I, U.S. interest in Venezuela was such that in 1925 about 20 companies held concessions there. Venezuela Gulf Oil Company and the Creole Syndicate undertook drilling in Lake Maracaibo, as did the Lago Petroleum Corporation, later acquired by Standard Oil (Indiana). In 1923 the British Equatorial Company struck oil in its Lake Maracaibo concession area, which the Lago Petroleum Company purchased in the following year. In 1928 Standard Oil Company (New Jersey) obtained a controlling interest in the Creole Petroleum Corporation (as the Creole Syndicate had been renamed), made it the holding company for its subsidiaries in Venezuela, and later acquired the Lago Petroleum Corporation, which had become a large producer in the Lake Maracaibo region. In 1932 the Lago properties were made part of the Creole Company, which for many years held first place among the oil producing companies of the world. In 1928 Venezuela occupied second place in world oil production for the first time. Although many companies searched for oil in Venezuela, three groups were conspicuously successful—Standard Oil Company (New Jersey); Royal Dutch/Shell; and Gulf Oil Corporation. For many years these groups accounted for well over half of Venezuela's oil production, which increased from 67,000 tons in 1920 to over 170,000,000 tons in 1963. Not until 1961 was Venezuela overtaken by Russia as the second largest producer in the world.

2. Middle East.—There was no U.S. stake in Middle Eastern oil until 1928, when participation in Iraq began. In 1919–20 the sequestered German shares of the Turkish Petroleum Company were assigned to the French government or its nominees so that the company was constituted as follows: Anglo-Persian, 47½%; Anglo-Saxon (Shell), 22½%; Compagnie Française des Pétroles, 25%; and Gulbenkian, 5%. The government of the United States protested. Insistence on the policy of the "open door" resulted in the D'Arcy Exploration Company (which Anglo-Persian had formed for participating in enterprises outside Persia) giving up half its share to a group of U.S. oil companies, receiving in return a royalty in the form of oil. The number of U.S. companies interested in participating varied. In 1928 five U.S. companies formed the Near East Development Corporation. These were Standard (New Jersey), Standard Oil of New York, Gulf Oil Corporation, Atlantic Refining and the Pan American Petroleum and Transport Company. In July 1928 the principals of the Turkish Petroleum Company were D'Arcy Exploration, 23¾%; Anglo-Saxon (Shell), 23¾%; Near Eastern Development Corporation (United States), 23¾%; Compagnie Française des Pétroles (CFP), 23¾%; and Gulbenkian, 5%. In June 1929 the Turkish Petroleum Company changed its name to the Iraq Petroleum Company, Ltd. (IPC).

In 1925 the Iraq government had granted to the Turkish Petroleum Company a concession with respect to Baghdad and Mosul

provinces. Two years later a spectacular oil strike was made near Kirkuk in northern Iraq. After the IPC's concession was revised in 1931 the company began the construction of a pipeline from the oil field to the Mediterranean. Two 12-in. lines ran together to the Euphrates, after which they separated—one branch went 532 mi. to Tripoli in Lebanon and the other 620 mi. to Haifa in Palestine. Opened officially in January 1935, this was the first of the great Middle East pipelines to the Mediterranean, and a remarkable engineering achievement.

In Persia the Masjed Soleyman field, producing 1,100,000 tons in 1919, exceeded 5,000,000 in 1928. In that year the Haft Kel field was discovered. Late in 1932 Riza Shah Pahlavi cancelled the concession. A new agreement was negotiated in 1933 and the company (renamed the Anglo-Iranian Oil Company, Ltd., in 1935, in accordance with Riza Shah's decree substituting "Iran" for "Persia") proceeded to enlarge the scope of its activities. Oil production from Iran exceeded 10,000,000 tons in 1937. In 1938 Iran as a producer was surpassed only by the United States, the U.S.S.R., and Venezuela.

In Bahrain, in the al Hasa province of what later became Saudi Arabia, and in Kuwait early interest in oil owed a great deal to the New Zealander Frank Holmes. Through the Eastern and General Syndicate, a company registered in London in 1920, Holmes hoped to sell to other organizations any concessions which he might acquire. He obtained in 1923 from King Ibn Saud permission to explore for oil in the al Hasa province; in 1924 from Ibn Saud and the ruler of Kuwait rights over the Neutral Zone; and in 1925 from the sheikh of Bahrain exploration rights covering the entire island. The first two concessions lapsed, but in November 1927 the Gulf Oil Corporation took over the option (due to expire on Dec. 7, 1927) from the Eastern and General Syndicate with respect to Bahrain. The Gulf Oil Corporation, as a member of the U.S. group associated with Turkish Petroleum, had agreed not to operate in Bahrain. This agreement went back to 1912, when the constituent groups of the Turkish Petroleum Company pledged, in the interests of orderly development, not to explore for or to develop oil anywhere in the Ottoman Empire except in association with one another. This principle was incorporated into the agreement dated July 31, 1928, to which a map was annexed showing, by means of a red line, areas in which participants in the Turkish Petroleum Company agreed not to compete with each other in exploration but to act collectively. Consequently, the Gulf Oil Corporation on Dec. 21, 1928, assigned its option rights over Bahrain to the Standard Oil Company of California, which in turn established a Canadian subsidiary (BAPCO) to hold and operate the concession. The Bahrain Petroleum Company discovered oil in 1932 and exports began in 1934.

The discovery in Bahrain had far-reaching effects in other Arab lands. Standard of California acquired from Ibn Saud rights in Saudi Arabia in 1933. Oil was struck in 1935 and exports began in 1939. In 1936 Standard of California sold to the Texas Company a half interest in its companies operating concessions in Bahrain and Saudi Arabia, as well as a half interest in other of its companies with rights in Sumatra, Java, and Netherlands New Guinea. In return Standard of California received certain payments and a half interest in Texas' marketing facilities in the Eastern Hemisphere. The California Texas Oil Company, Ltd., ("Caltex"), jointly owned by the two parent groups, was incorporated in 1936. Initially its function was marketing in the East. In January 1947 Texas sold its marketing outlets in Europe and North Africa to the California Texas Company. Subsequently the latter company built refineries in several European countries which were supplied with Middle Eastern crude oil.

In Kuwait a contest between the Anglo-Persian Oil Company and the Gulf Oil Corporation to secure a concession was resolved by the formation in February 1934 of the Kuwait Oil Company, representing equal participation by the two groups, and by a grant by the ruler of Kuwait in December 1934 giving the Kuwait Company rights covering the entire area. The first drilling efforts failed, but in April 1938 a field of vast potentiality was discovered in the Burgan area. Development, suspended during World War II, was resumed in 1945 and in the following year the first cargo was loaded for export. In Qatar, a peninsular sheikhdom on the eastern side of Saudi Arabia, an associate of Iraq Petroleum Company opened up the Dukhan field late in 1938. World War II brought a cessation of activity and oil was not exported until the end of 1949.

Although the oil industry was established in several Middle Eastern countries before World War II, the total production of that region in 1938 amounted only to 15,000,000 tons out of a total world production of 274,000,000 tons. The largest producers were the United States with 168,000,000 tons, Venezuela with 28,000,000, and the U.S.S.R. with 28,000,000. Iran ranked fourth but only accounted for about 4% of the total world crude production. Following Iran were the Netherlands East Indies, Rumania, Mexico, Iraq, Colombia, and Trinidad. During the years 1901–40 the United States accounted for 64% of the world's production; from 1926 to 1930 discoveries in Oklahoma, Texas, and California more than doubled the known reserves of the country. Russia produced, in the years 1901–40, about 10% of the world's total production; Europe, excluding Russia, produced about 3% of the total, the most important country being Rumania, which in 1938 had an output of about 4% of that of the United States. In the years between the wars, development in Rumania was such that in 1934 the production figure was 8,467,000 tons. The country ranked fourth in the world in 1935. In the Western Hemisphere, outside the United States, the biggest producer was Venezuela, where production had begun in 1917. By 1938 Venezuela was contributing approximately 10% of the world's total. In Mexico production had risen spectacularly from 1919–21, reaching in the latter year 25% of the world's entire production, but a sharp decline ensued. In 1938 Mexico expropriated the foreign oil companies. Final payment for properties expropriated was made in 1962.

C. After World War II

World War I established petroleum as an essential war material. In World War II the need for petroleum and its products reached what were then monumental proportions. Consumption during the war years accounted for one-fifth of the total production of the United States up to that time. In the latter part of the war the tonnage of petroleum products being shipped overseas by the United States was nearly double that of all other tonnage combined, including arms, equipment, food, medicine, and men. The war brought demands for many new products and constantly changing specifications. A B-29 aircraft alone used 20 different oil products. The air war demanded large quantities of 100-octane fuel, so that production increased from 75,000 bbl. daily in 1942 to nearly 600,000 in mid-1945. Oil supplied toluene for explosives and asphalt for landing strips and roads. The war brought new developments in pipeline technique, such as the 24-in. war emergency line and the 20-in. products line, each running from points in Texas to the Atlantic seaboard. After the war both were converted to natural gas transportation. In Europe by means of Pipe Line Under The Ocean (PLUTO) 1,000,000 gal. of gasoline daily was reaching France from England by 1945. In the Middle East expansion took place rapidly after the reopening of the Mediterranean to tanker traffic in 1943. In 1944 the refineries in the Middle East were turning out 89% more petroleum products than in 1938. In Iran, production, which had fallen to 6,605,000 tons in 1941 (from over 10,000,000 in 1938), reached 16,839,490 tons in 1945.

1. Middle East Development.—In the postwar years the search for oil intensified, with new companies and new nationalities represented. The most spectacular developments occurred in the Middle East, but notable results were also obtained in other areas such as North Africa, Canada, and Nigeria. The geologist E. De Golyer had estimated in 1944 the proved and semiproved reserves of the Middle East at about 18,000,000,000 bbl., an estimate which he revised upward in 1948 to a 32,000,000,000 bbl. minimum. With the new knowledge available, the "published proved" reserves for the Middle East were, in 1962, put at 194,000,000,000 bbl., or 61.1% of the world's total.

In Saudi Arabia, the California Arabian Standard Oil Company,

after 1944 known as the Arabian American Oil Company, or Aramco, had not been shut down during the war. A 50,000-bbl.-per-day refinery, completed at Ras Tanura, began operations in September 1945. Development in Saudi Arabia brought changes elsewhere. Standard Oil (New Jersey) and Socony-Vacuum obtained a 30% and a 10% interest, respectively, in Aramco and in Tapline, the company formed to build a 1,000-mi. pipeline from the Arabian fields near the Gulf to the Mediterranean port of Sidon, Lebanon. The project was completed in 1950. Saudi Arabia has one of the largest proved reserves in the world. In 1963 its production was surpassed by the United States, the U.S.S.R., Venezuela, and Kuwait.

Oil from new fields in southern Iraq was first exported in 1951, via the Persian Gulf. The resumption of operations in Kuwait was followed by phenomenal growth, one of the factors being the reduced availability of Persian oil from 1951 to 1954. Production rose from 2,185,308 tons in 1947 to 17,000,000 tons in 1950 and surpassed 37,000,000 tons in 1952. By 1953 Kuwait had overtaken Saudi Arabia as a producer and retained first place in the Middle East since that time to 1963 when it produced more than 90,000,000 tons.

In Iran, too, expansion characterized the postwar years, with production in 1950 reaching 32,000,000 tons. But events occurring in the summer and autumn of 1951 brought the Iranian oil industry to a standstill. In April 1951 Mohammad Mossadegh became prime minister, and oil was declared nationalized under a National Iranian Oil Company. Many efforts were made to resolve the deadlock, but no settlement was possible until after Mossadegh had been replaced in August 1953.

Late in 1953 the Anglo-Iranian Oil Company invited a number of major international oil companies, all with experience in the Middle East, to form a consortium for the purpose of reactivating the oil industry in conjunction with the National Iranian Oil Company (NIOC). The companies that originally formed the consortium, and their respective interests, were: Anglo-Iranian, 40% (name later changed to the British Petroleum Company, Ltd.); N. V. De Bataafsche Petroleum Maatschappij (representing the Royal Dutch/Shell group), 14%; Gulf Oil Corporation, 8%; Socony-Vacuum, 8%; Standard Oil Company (New Jersey), 8%; Standard Oil Company of California, 8%; the Texas Company, 8%; and Compagnie Française des Pétroles, 6%. Subsequently, each of the five U.S. companies transferred 1% of its holdings to a group (Iricon) of nine smaller U.S. companies. Discussions which began in Teheran in April 1954 between representatives of the consortium and the Iranian government resulted in an agreement on an essentially 50/50 profit-sharing basis. The agreement, ratified by the Iranian government in October 1954, enabled Iran to reoccupy a major position in the world oil industry with a production in 1963 of 73,000,000 tons as compared with approximately 32,000,000 in 1950 and only 2,000,000 in 1954.

The 50/50 profit-sharing formula (owner government and operating company each receiving half of operating profits) was first instituted in Venezuela in 1943, coming into operation there in 1948. Aramco introduced the concept into Saudi Arabia by an agreement which came into force in December 1950, and similar arrangements were made with Kuwait in 1951, Iraq early in 1952, and then in Bahrain and Qatar. The 50/50 basis subsequently became widely accepted both by the governments of producing countries and by the major operating companies.

2. Social Benefits from Oil Revenue.—In many of the major petroleum-producing countries oil revenue forms a very substantial part of the national income. Revenues from oil, as well as direct efforts by the oil companies themselves, have provided the means to fight diseases such as malaria in Venezuela and trachoma in the Middle East and have made possible the building of schools and hospitals and the introduction of industrial and agricultural improvements on an unparalleled scale. Since oil often occurs in undeveloped areas the oil companies themselves have had to build roads. Kuwait has provided a striking example of the transformation which can be brought about by the responsible use of oil royalties.

3. New Pattern of World Development.—Significant changes have taken place in the pattern of oil development. More companies have overseas or worldwide interests. The American Independent Oil Company (Aminoil, a combination of ten U.S. companies and individuals) obtained in 1949 from the ruler of Kuwait a concession covering that country's undivided half interest in the Neutral Zone. Shortly thereafter J. Paul Getty's Pacific Western Oil (name changed to Getty Oil Company in 1956) of Los Angeles signed an agreement with Saudi Arabia covering its interest in the Neutral Zone. This marked the beginning of a new trend which brought many companies to the Middle East for the first time. In 1958 the Japan Petroleum Trading Company Ltd. received from the governments of Saudi Arabia and Kuwait concessions over offshore areas of the Neutral Zone and formed a subsidiary, Arabian Oil Company Ltd., as an operating company. Iran also granted concessions outside the consortium area. As a result of the petroleum law of 1957 the NIOC concluded agreements both with the Italian state-owned Agip Mineraria S.p.A. (AGIP) and with a subsidiary of Standard (Indiana). Nor was such new activity limited to the Middle East. The amendment of its petroleum law by Libya in 1955 brought applications from 13 companies. The success of Esso Standard Libya Inc. with its Zeltan find in 1959 foreshadowed the rise of still another country as a major producer. North Africa and the Sahara were completely transformed in the space of a few years from a region of doubtful promise to one of intense activity. In 1963 Algeria, enjoying the fruits of the pioneer work of the French government and of oil companies in the Sahara after the end of World War II, produced over 23,000,000 tons; and Libya, where production began only in October 1961, produced 21,000,000 tons in 1963.

Drilling in marine areas became widespread following the end of World War II. As early as 1911 the Gulf Refining Company drilled a well in Caddo Lake on the Louisiana-Texas border. Overwater drilling on Venezuela's Lake Maracaibo was successfully undertaken in the 1920s and this area subsequently was extensively developed. In 1951 Creole Petroleum was operating 1,500 wells in Lake Maracaibo alone. The first offshore well in the Gulf of Mexico was begun in 1937 as a joint operation of the Superior Oil Company and Pure Oil Company. Completed in 1938, it was the first commercial oil discovery in the Gulf of Mexico.

In the Persian Gulf, Aramco was the first company to undertake marine work, and the result was the discovery of the great Safaniya field in 1951. In 1962 the Safaniya field provided nearly one-fifth of Aramco's output of 75,000,000 tons. Aramco's other offshore field, Manifa, was brought into production in 1964. The Japanese-owned Arabian Oil Company Ltd. progressed rapidly with work in the offshore areas of the Neutral Zone and struck oil in 1960. Shipments commenced in 1961 from the Khafji underwater field. Exports began in 1962 from the Umm Shaif field (about 60 mi. off the coast of Abu Dhabi) which was developed by Abu Dhabi Marine Areas Ltd. (two-thirds British Petroleum and one-third CFP). The Pan American International Oil Company, which in 1962 became the American International Oil Company (a subsidiary of Standard Oil Company [Indiana]), discovered oil off Kharg Island through its Iran Pan American Oil Company (IPAC) venture. In 1963 the Continental Oil Company, which became a major producer in Libya, obtained concessions over both onshore and offshore areas of Dubai and of Qatar. Although the most successful results were achieved in Lake Maracaibo, the Gulf of Mexico, and the Persian Gulf, marine operations were being carried on in many other parts of the world, from Brunei to the Cook Inlet Basin of Alaska. A great deal of interest was being shown in the prospects of drilling in the North Sea in the mid-1960s.

In the Western Hemisphere the United States and Venezuela over the years retained their positions as the world's two largest producers. In Canada, where interest in the oil industry was shown as early as in the United States, the results were not encouraging until the discovery in Alberta of the Leduc field in 1947, followed by Redwater in 1948. These developments radically changed the outlook of the industry in Canada. Production increased from 8,000,000 tons annually in 1952 to 36,000,000 tons in 1963. Exploration was carried out intensively by many companies, but the industry by the mid-1960s had not regained the

investment made following the Leduc discovery. Investment in the Canadian oil industry in the years from 1948 to the end of 1962 amounted to $6,600,000,000 against $5,500,000,000 income. The possibilities of the Arctic islands and the Athabasca tar sands attracted considerable interest.

Another changing factor in the world oil picture of the 1960s was the position of the U.S.S.R. At the turn of the 20th century Russia's production surpassed that of the United States for a period of four years (1898–1902) when Swedish, Dutch, British, and French capital was freely invested there. After the 1917 Revolution and the confiscation of foreign assets the country's production fell sharply. When it rose again state policy directed that petroleum resources be used in the main for domestic purposes, largely military. This policy changed in 1953 when the U.S.S.R. again began to export oil. In 1962 it exported 45,000,000 tons (including 25,000,000 tons to non-Communist countries) out of a production of 186,000,000 tons, and it was planned to increase oil production on a large scale. The Perm, Ufa, Kuybyshev area west of the Urals supplanted the Apsheron Peninsula as the major producing area, and substantial new discoveries were reported in Azerbaijan, the Ukraine, and in particular in the central Asian provinces.

In 1945 Rumania came under Soviet influence, with the subsequent nationalization of oil properties. In the span of just over a century, from its first recorded production in 1856 of 275 tons to 1962, Rumania had a cumulative production of some 285,000,000 tons. Production had become stable at about 12,000,000 tons a year by the beginning of the 1960s.

The modern petroleum industry, since Drake's Titusville well of 1859, has undergone periods of significant change. In its first half-century, the U.S. industry, latterly guided by Rockefeller, had the foremost influence, worldwide in scope. In this period, too, petroleum products were used mainly as illuminants. During the next half-century the most notable developments were the use of petroleum products as a source of power and heat, and the geographical shift of supply sources to the Middle East, following discovery and development there of new fields and extensive reserves.

PETROLEUM WAXES. Petroleum provided the first abundant source of inexpensive waxy materials. Such waxes were among the earliest products made from petroleum, and their production continued in increasing quantities as new uses were found for them. Although these products represent in volume less than 1% of the crude petroleum refined, they are highly important in terms of their versatility in meeting an increasing number of human needs. The petroleum industry has constantly striven to develop new wax grades and large-scale, low-cost methods for preparing them. In contrast, animal and vegetable waxes continue to be high in cost and of varying chemical character and uncertain availability.

Petroleum waxes are classified in three groups: paraffin, microcrystalline, and synthetic waxes. Materials in the last group are arbitrarily included here because their properties and uses are similar to those of the first two groups, even though the synthetics are made from coal instead of petroleum. Microcrystalline waxes are differentiated from the paraffins by their greater viscosities, higher melting points, and poorly defined crystalline structure; the paraffin waxes are obtained from the lighter fractions of petroleum while microcrystalline waxes come from the heavier fractions.

Paraffin was first produced commercially in 1867, less than ten years after the drilling of the first petroleum well. Microcrystalline wax became commercially available in 1932, while synthetic paraffin prepared by the Fischer-Tropsch reaction technique (described below) has been available only since 1947.

Paraffin Waxes.—Prior to 1867, limited amounts of paraffin wax were prepared from bituminous shales for use in candle making. Even then the demand exceeded the supply because the distillation process was slow. In contrast, paraffin separation from petroleum required only chilling and filtration. The earliest paraffin-wax separation was effected by hanging canvas bags of chilled oil in a large icebox. The separated wax stayed in the bag much as does the pomace in fruit-juice production.

Basically, paraffin and microcrystalline waxes are still made in the same way. Huge modern plants and automated processing equipment do the same operations: chill the oil until the naturally occurring waxy components solidify and then filter-separate them from the fluid oil, which is recovered for other purposes. Technical progress has made the separation more efficient and less costly. To this processing have been added methods of purification by chemical treatment, decolorization by adsorbents, and fractionation of the separated waxes into grades by distillation or recrystallization, or both. Also, new crude oils with higher wax content have been discovered and earmarked for this production. But even the most modern of petroleum-wax plants is simply an extension and refinement of the methods utilizing canvas bags.

"Slack" wax was the term given to paraffin wax as it was recovered by the original methods. This grade frequently retained as much as 20% oil. When its oil content is reduced to about 3%, it is referred to as "crude scale" wax. This wax, after some decolorization, becomes "white crude scale" wax and is sold as such for many uses. Further purification improves the colour, odour, and taste, and limits the melting-point range to about 2° F (1° C) yielding "fully refined paraffin" wax. This is the generic commercial name irrespective of the refining method used.

Paraffin wax is a solid, crystalline mixture of straight-chain or normal hydrocarbons ranging in molecular weight from C_{20} to C_{30} and possibly higher. It is distinguished by its solid state at room temperature, relatively slight deformation at this temperature even under considerable pressure, and low viscosity when melted. Paraffin-wax crystals are long, narrow, and form in plates. Fully refined paraffin grades are dry, hard, and capable of imparting good gloss.

Modern commerce generally recognizes two degrees of paraffin wax refinement, crude scale and fully refined. Crude scale paraffin ranges in melting point from 118° to 135° F (48° to 57° C) and contains about 0.5% oil. Fully refined paraffin has a melting point range of 118° to 150° F (48° to 66° C), is colourless, odourless, and tasteless, and contains about 0.2% oil (standards established by the American Society for Testing Materials).

Synthetic Paraffin Wax.—The period after World War II

saw the introduction of the first commercially available synthetic paraffin waxes, produced by the Fischer-Tropsch reaction technique. In the Fischer-Tropsch synthesis, coal is burned in gas generators in the presence of oxygen and steam to produce a gas stream composed mainly of carbon monoxide and hydrogen. After purification, this gas stream is converted to hydrocarbons in the presence of a magnetic iron catalyst. Following removal of the catalyst, the resultant liquid hydrocarbons are refined and separated.

One of the products thus obtained is paraffin wax, snow-white in colour, harder than petroleum paraffin, and capable of taking a high gloss, the degree of gloss being one of the factors used in judging wax quality. The average molecular weight approximates 750, corresponding to 50 to 55 carbon atoms. Its unique character and high purity well suit it as a replacement for certain vegetable waxes and as a modifier for petroleum waxes and for some plastics, such as polyethylene. Also, synthetic paraffin wax may be oxidized to yield pale yellow, hard waxes composed of mixtures of high-molecular-weight oxygenated compounds, chiefly carboxylic and waxy acids and esters. Their unique value lies in their ability to saponify with aqueous solutions of organic and inorganic alkalies such as borax, sodium hydroxide, morpholine, and triethanolamine. These aqueous wax dispersions serve admirably as heavy-duty floor wax, for waterproofing textiles and paper, in the tanning of leather, as metal-drawing lubricants, as rust preventives, and for masonry and concrete treatment. Thus, in general, synthetic paraffin, both straight and in the oxidized form, complements rather than supplants the petroleum-derived material.

Microcrystalline Waxes.—Although the raw material from which microcrystalline waxes are separated was always present in petroleum, the introduction of these unique materials had to await other industry developments to make their separation commercially feasible. This occurred about 1930. Previously, when the heavy fractions of petroleum were used as lubricants, there was little need that they be well refined or that they be fluid at low temperatures. However, the increasing use of the motor car changed this. Crankcase lubrication demanded that the oil flow easily at low temperatures and that it have minimum tendency to carbonize in the cylinders. Wax removal was essential. Methods of separation included solvent dilution, chilling, and centrifuging, and varying combinations of these. The quality and quantity of the removed material that became available encouraged study which led to commercial production of microcrystalline waxes.

In contrast to paraffin wax, the microcrystalline grades vary widely in physical character, depending on the crude-oil source and the degree and method of refinement. Some are as ductile as beeswax, others are hard and brittle, and still others lack cohesive strength and tend to crumble easily during handling. The melting point range is higher than that of paraffin, commercial grades ranging from 145° to 200° F (63° to 93° C). In colour microcrystalline wax ranges from dark brown to cream white. Decolorization is always difficult and odour and taste have long been deterrents to the acceptance of microcrystalline wax, especially in the packaging of foods.

Petroleum Wax Uses.—From the beginning, candle making has been a large petroleum-wax consumer. While progress in artificial illumination might seem to have relegated the candle to a minor place, its utility as a portable, self-contained source of light continues. Candle production, including candles for religious and decorative uses, still requires millions of pounds of petroleum wax each year, for paraffin wax, combined with varying amounts of stearic acid, is a satisfactory material for all candles except those for liturgical use that are required to contain some beeswax.

The paper industry is by far the largest single user of petroleum wax, especially microcrystalline waxes. Chemical purity and low cost, along with freedom from odour and taste, excellent moisture-vapour and water resistance, and relative inertness, led to early widespread use of paraffin in all types of food packaging and in food handling.

Petroleum wax may be applied to the paper pulp before it is formed into sheets or after the sheet is made. Frequently, enough wax is applied to serve also as the wrapper adhesive, as in bread wrapping. In the case of dynamite, the paper is waxed both before and after the stick is formed to secure added protection against moisture.

The match industry was an early user of paraffin wax. In the wooden match, the paraffin coating impregnates the wood just below the head; it is visible after the match is struck as a clear liquid flowing away from the head as the stick is consumed. In the paper match, the paraffin-treated portion of the stick is clearly darker just below the head. In both cases, the wax helps ignite the match stick by supplying an easily vaporized hydrocarbon fuel.

PETROLOGY is the branch of geology concerned with the investigation of the composition, structure and history of the rock masses building up the accessible portions of the earth's crust (Gr. *petros*, "rock"). Rocks are usually defined as aggregates of minerals without reference to their state of cohesion. Loose sands, clays, gravels or soils are included among rocks as being mineral masses playing an important role in field geology. On the other hand, the less soluble parts of the skeletons of animals and plants may form a considerable portion of rocks as, for example, in the case of coral limestone, lignite and chalk. Lastly, rocks may be built up almost wholly of noncrystalline material such as obsidian, pitchstone or tachylyte, representing liquids so rapidly chilled that consolidation has occurred in the glassy state. Rocks are the units with which the geologist deals in investigating the structure of the earth's crust, and some varieties cover enormous areas. Granite, sandstone and schist often form whole provinces and build up lofty mountains, while other rock types are of such rare occurrence that they are known only in one or two localities in far-removed parts of the earth's surface.

Broadly speaking, rocks are divided into three great classes, igneous, sedimentary and metamorphic. In this article discussion is confined to the nature, composition, classification and origin of igneous rocks and the methods by which they are examined. For the other groups, *see* SEDIMENTARY ROCKS and METAMORPHISM. *See* also MINERALOGY.

Following are the main subdivisions of this article:

I. Treatment of the Subject
  1. Composition of Igneous Rocks
  2. Magma

VII. Geographic Distribution of Igneous Rocks

I. TREATMENT OF THE SUBJECT

Below is a brief survey of that part of the science of petrology which concerns igneous rocks, with the headings under which particular subjects are treated (each italicized item has a separate article).

Igneous rocks occur as intrusions or extrusions. The plutonic or deep-seated intrusive rocks which cooled far below the surface occur as *batholiths*, bosses, *laccoliths* and *veins* (*see* ORE DEPOSITS), and include *granite*, *syenite*, *diorite*, *gabbro* and *peridotite*: related to the granites are *aplite*, *greisen*, *pegmatite* and *schorl*; to the syenites, borolanite, *monzonite*, *nephelite-syenite* and *ijolite*; to the diorites, *tonalite*; to the gabbros, *napoleonite*, *pyroxenite* and *theralite*, and to the peridotites, *picrite* and *serpentine*. The hypabyssal intrusive rocks occur as *sills*, *veins*, *necks*, etc., and are represented by *porphyry* and porphyrite, *diabase* and *lamprophyre*; to the porphyries belong *felsite* and *quartz porphyry*. The extrusive rocks are volcanic and found typically as lava flows; they include *obsidian*, *perlite*, *pitchstone* and *rhyolite*, *phonolite* and *trachyte*, *andesite*, *dacite* and *basalt* (with the related *spilite*, *tachylyte* and *variolite*), *nephelinite* and tephrite.

Intermediate between the sedimentary and igneous rocks comes the group of rocks known as pyroclastic or fragmental volcanic rocks. These include *agglomerate*, some types of *breccia* and *tuff* (*see* also VOLCANO). The agencies which affect igneous (among other) rocks and modify them are discussed under GEOCHEMISTRY, METAMORPHISM, METASOMATISM and VOLCANISM.

1. Composition of Igneous Rocks.—Though the number of recognized minerals approximates 1,500, comparatively few of these are important as rock formers, more especially if the subdivisions into which the common species are broken up are disregarded. The vast majority of the igneous rocks are built up of less than a dozen groups of minerals. These are: (1) quartz; (2) feldspars; (3) pyroxenes; (4) amphiboles; (5) micas; (6) olivines; (7) nephelite; (8) leucite; (9) iron ores; and (10) apatite. To this list, for sedimentary rocks, may be added chlorite, kaolin, montmorillonite, calcite, dolomite and a few other minerals. Metamorphic rocks are built up largely of the same minerals as igneous rocks but include special species which are foreign to the latter, partly on account of their composition and partly because they appear to require special physical conditions (stress) for their production. The mineralogical nature of a rock is primarily dependent on its chemical composition, but other factors are of first importance in determining the paragenesis of rock-forming minerals, principally the mode of origin of the rock or the physical conditions prevailing during its formation. Two rock masses may have very much the same bulk composition and yet differ fundamentally in their mineralogical assemblages. Thus, certain lamprophyres rich in biotite have much the same composition as certain leucite-basalts, a hornblendite may be similar in composition to a camptonite and so on. Igneous rocks of identical chemical composition but dissimilar mineralogical constitution are said to be heteromorphous. The governing factors are the physical conditions attending consolidation of the rock.

All crystalline rocks have consolidated from solution or from fusion. A granite arises by the consolidation of a liquid at high temperatures and great pressures; a metamorphic rock like mica schist, on the other hand, represents the recrystallization product of a clay rock under the influence of heat and stress. Throughout this conversion the rock has been essentially solid, recrystallization taking place in the presence of minor amounts of interstitial liquid. Other crystalline rocks, like rock salt, gypsum, anhydrite, etc., have been deposited from solution in water, mostly as a result of evaporation on exposure to the air. The majority of sedimentary rocks, however, consists of a mechanical aggregate of crystalline particles; such are sandstone, clay, etc. The structure of these sedimentary and all pyroclastic rocks is referred to as fragmental.

2. Magma.—All igneous rocks have solidified from a state of liquidity, the liquid that finally consolidates as rock being technically referred to as magma (Gr. *magma*, from *massein*, "to knead"). Rock magma is a complex silicate solution carrying gases; the most important part of the solution is water, which may constitute 5% to 6% of the mass. The greater part of the clouds given off by active volcanoes consists of steam, with which are associated minor amounts of other gases, the chief being carbon dioxide, carbon monoxide, hydrochloric acid, sulfur vapour, oxides of sulfur, hydrogen sulfide, hydrogen fluoride, ammonia, methane, chlorine, fluorine, hydrogen and nitrogen. When the magma consolidates the major part of these volatile constituents usually escapes. With very rapid cooling, however, the magma may solidify without crystallization as a volcanic glass, at the same time retaining much of its water. Analyses of pitchstone show not infrequently a content of 5% to 6% of water, and even higher values are recorded; on the other hand unaltered crystalline igneous rocks seldom show a water content greater than 2%. Here there is almost direct confirmation of the conclusion that the water content of the magma before crystallization is greater than the water content of the rock formed from it.

From what source is igneous magma derived? In the older conception of the earth a volcano was pictured as a safety valve for a molten interior, but a close study of igneous action, past and present, clearly negates any such interpretation. The active vents of Mauna Loa and Kilauea, Hawaii, though only about 20 mi. apart, have the summits of their lava columns at a difference of level of 10,000 ft. Yet liquid lava is erupted more frequently and in greater quantity from the higher column. Clearly these two outlets are not directly connected with a common liquid reservoir. Again, neighbouring vents, as those of the Lipari Islands north of Sicily, erupt widely different products, and each may maintain its independent behaviour regardless of what is happening to its neighbour. The conclusion is enforced that each distinct eruptive centre possesses its own reservoir, and the presence of a number of independent magma chambers underlying an eruptive region is indicated. At greater depth these are no doubt connected with some magmatic reservoir of much larger dimensions. In some such common source the close community of petrographic character revealed in the succession of liquids erupted or intruded throughout any given igneous cycle is to be traced.

II. METHODS OF INVESTIGATION

A. ANALYTICAL

1. Macroscopic Characters.—The macroscopic (Gr. *makros*, "large") characters of rocks, those visible in hand specimens without the aid of the microscope, are extremely varied and difficult to describe accurately and fully. The geologist in the field depends principally on them and on a few rough chemical and physical tests; and to the practical engineer, architect and quarrymaster they are all-important. Although frequently insufficient in themselves to determine the true nature of a rock, they usually serve for a preliminary classification and often give all the information really needed for a particular purpose. With a small bottle of acid to test for carbonate of lime, a knife to ascertain the hardness of rocks and minerals and a pocket lens to magnify their structure, the field geologist is rarely at a loss in deciding to what group a rock belongs. The fine-grained species may be indeterminable by these means, and the minute mineral components of all rocks can usually be ascertained only by microscopic examination; but it is easy to see that a sandstone or grit consists of more or less rounded, waterworn sand grains, and if it contains dull, weathered particles of feldspar, shining scales of mica or small crystals of calcite, these also rarely escape observation. Shales and clay rocks generally are soft, fine-grained, often laminated, and they not infrequently contain minute organisms of fragments of plants. Limestones are easily marked with a knife blade, effervesce readily with weak cold acid and often contain entire or broken shells or other fossils. The crystalline nature of a granite or basalt is obvious at a glance, and while the former contains white or pink feldspar, clear vitreous quartz and glancing flakes of mica the other will show yellow-green olivine, black augite and gray striated plagioclase.

2. Microscopic Characters.—When dealing with unfamiliar types or with rocks so fine-grained that their component minerals cannot be determined with the aid of a lens, the geologist is obliged to have recourse to more delicate and searching methods of inves-

tigation. With the aid of the blowpipe (to test the fusibility of detached crystals), the goniometer (to measure crystal angles), the magnet, the magnifying glass and the specific gravity balance the earlier investigators attained surprisingly accurate results. Examples of these may be found in the works of Leopold von Buch, G. P. Scrope, Charles Darwin and many others. About the end of the 18th century D. S. G. de Dolomieu examined crushed rock powders under the microscope and P. L. Cordier in 1815 crushed, levigated and investigated the finer groundmass of igneous rocks. His researches are models of scrupulous accuracy, and he was able to announce that these rocks consisted essentially of such minerals as feldspar, augite, iron ores and volcanic glass and did not differ in nature from the coarser grained rocks. W. Nicol, whose name is associated with the discovery of the Nicol prism, seems to have been the first to prepare thin slices of mineral substances, and his methods were applied by H. Witham (1831) to the study of plant petrifactions.

Petrography.—This method, subsequently of such far-reaching importance in petrology, was not immediately used for the systematic investigation of rocks, and it was not until 1858 that H. C. Sorby pointed out its value. The great work of this investigator was the production of very thin sections of rocks and their systematic examination under the high powers of the microscope. The densest, blackest rock can be made to yield a section of $\frac{1}{1,000}$ in. in thickness, so thin and transparent that fine print can be easily read through it and transmitting light so clearly that the most high-powered objectives of the microscope can be used to discern and study its minutest structures with the same facility that they can be employed upon sections of organic material prepared by the microtome. The introduction of this powerful weapon of research inaugurated a new era in petrology—that of petrography or the descriptive branch of petrology. The optical study of sections of crystals had been advanced by Sir David Brewster, Nicol and other physicists and mineralogists and it only remained to apply their methods to the minerals visible in rock sections. The pioneer workers who brought quantitative methods into the optical side of the problem were A. des Cloizeaux, K. H. F. Rosenbusch, F. Zirkel, M. Schuster, F. Fouqué and Auguste Michel Lévy.

By the second half of the 20th century optical methods for determining minerals with the petrographic microscope were highly developed.

Optical Constants.—Although rocks at mid-20th century were studied principally in microsections, the investigation of fine crushed rock powders, which was the first branch of microscopic petrology to receive attention, was still in use. A mineral whose optical properties are known can be accurately determined by immersing its powder in liquid media whose indices of refraction are known, and determining the optical constants. In the hands of a skilled petrographer the principal optical constants of a single grain of a mineral can be determined in half an hour. The chief fundamental constants measured are the principal indices of refraction, the crystallographic orientation of the directions of light vibration corresponding to those indices and the amount of absorption of light vibrating in these directions, all for one or more standard wave lengths of light. The double refraction, optical character, optical axial angle, dispersion of the optic axes and bisectrices and extinction angle are all fixed by the fundamental constants and can be estimated under the microscope.

The immersion media cover a range of optical refraction from that of water (1.333) to that of a selenium-arsenic selenide melt (3.17). The liquids are chiefly organic substances—acetone, alcohol, cinnamon oil and methylene iodide. Most minerals have refraction constants ranging in the interval 1.450–1.870, and their refractive indices may therefore be matched by a set of liquids whose refractions cover this range. The modern rotation apparatus whereby thin sections may be tilted from the horizontal so that the axis of the microscope passes through them at different angles has been of inestimable value in measuring accurately the optical constants of a single grain in a rock slice, and is widely used for the determination of feldspar and other mineral species of variable composition. A few measurements on a selected section of a mineral permit the determination of its exact chemical composition and the crystallographic orientation of the section itself. The technical methods employed for the determinations referred to above are largely founded on the use of polarized light.

3. Mechanical Separation of Constituents.—The separation of the constituents of a crushed powder in order to obtain pure samples suitable for analysis is also extensively practised. The two principal methods adopted involve either the electromagnet or heavy liquids.

By the use of an electromagnet the component minerals of a rock may be separated by varying the strength of the current. A weak magnetic field attracts magnetite, then hematite and ilmenite. Silicates containing iron will follow in definite order, augite, hornblende, tourmaline, olivine and biotite being successively attracted. The degree of attraction is not, however, proportional to the iron content. The colourless nonmagnetic minerals—quartz, feldspar, muscovite, nephelite, etc.—remain. In the modern laboratory, processes using automatic magnetic separators supplement or replace magnetic separation by hand. Electrostatic and dielectric methods of separation have also been brought into use in the isolation of mineral particles of rocks.

Separation by means of water is not much used in petrographic work. However, a preliminary "panning" as practised by miners is often useful as a means of concentrating rare minerals occurring in very small quantity in the rock before the application of the methods next to be described. Methods of separation of minerals by which they are sorted according to their specific gravities (sp.gr.) by means of heavy fluids have an extensive application. The fluids used are those which do not attack the majority of the rock-forming minerals.

Of the many liquids used, methylene iodide (sp.gr. 3.32) and bromoform (sp.gr. 2.86) are perhaps the most convenient. For more dense minerals, Clerici's solution—an aqueous solution of thallium formate—is best adopted. By concentration the specific gravity can be raised to 4.32 at 60° C. so that even the heavier rock minerals can be separated without difficulty. By dilution with water, or, in the case of methylene iodide, dilution with bromoform or benzol, successive crops of minerals may be separated in appropriate separating funnels. In this way a granite may be successively fractionated into its component minerals, biotite (sp.gr. 3.1), muscovite (2.85), quartz (2.65), oligoclase (2.64) and orthoclase (2.56). All these minerals float in methylene iodide; on dilution with benzol they are precipitated in the order given. Rocks like eclogite containing heavier minerals, such as ilmenite (sp.gr. 4.84), garnet (4.20) and diopside (3.29), may be similarly separated by means of a thallium formate-water solution. Mineral isolation using heavy liquids is commonly carried out with high-speed centrifuges, which greatly hasten settling, especially of the finest particles, and effect a more thorough separation of the minerals.

4. Microchemical Methods.—Chemical methods are frequently of great use. Weak hydrochloric acid will dissolve calcite from a crushed limestone, leaving dolomite and silicate minerals, and hydrofluoric acid may be used to extract the glassy base of volcanic and hypabyssal rocks from the pyroxenic minerals. Of much wider use, however, are microchemical methods for distinguishing minerals under the microscope. They are of special value in discriminating alkali minerals like nephelite, haüynite, noselite, analcite and sodalite in the groundmass of igneous rocks. The methods depend on selective attack by acids, the formation of distinctive precipitates and the staining of gelatinous residues. Quartz and feldspar in fine-grained rocks may be differentiated by etching with hydrofluoric acid; quartz remains clear while the surface of the feldspar grain becomes cloudy, being altered to aluminum fluosilicate, and may be stained by an aniline dye. This method is particularly useful in discriminating quartz and feldspar in fine-grained metamorphic rocks in which the feldspar is without crystal form, is untwinned and shows lack of cleavage.

5. X-ray Methods.—X-ray diffraction methods of identification have also come much into use; they may be applied to single crystals, isolated by the procedures already outlined, or to the finest aggregates, using then the technique of X-ray powder photography. (*See* MINERALOGY: *X-ray Diffraction;* X-RAYS.)

6. Chemical Analysis.—The ultimate chemical composition of a rock is of fundamental importance in determining its nature, and the chemical analysis of rocks is now widely carried out. In rock analysis of the better class as many as 25 constituents are determined and recorded. The most abundant or major constituents are stated as oxides, and any rock analysis of good quality records the content of at least nine or ten of these. They are silica, alumina, ferric and ferrous oxides, magnesia, lime, soda, potash and water. These nine oxides make up about 98% of the igneous rocks. Two other oxides are usually determined, TiO_2 and P_2O_5, as they are represented in the common minor constituents—ilmenite and apatite—titanium being also present in some pyroxenes, amphiboles and micas. Such a chemical analysis is usually sufficient to determine to which of the two great classes, igneous or sedimentary, a rock belongs and, if it is igneous, the position to be assigned to it in any of the conventional classifications. In the case of metamorphic rocks it often establishes whether the original mass was a sediment or of igneous origin.

7. Specific Gravity.—By the balance and the pycnometer the specific gravity of rocks is determined in the usual way. It is greatest in those rocks rich in iron, magnesia and the heavy metals, and least in rocks rich in alkalies, silica and water. Eclogites (sp.gr. 3.5) are among the heaviest of the silicate igneous rocks, while the vitreous lavas of high silicity like obsidian (sp.gr. 2.35) are among the lightest.

B. Rock Synthesis

The methods of investigation described above may be grouped together as analytical, in contradistinction to the synthetic investigation of rocks, which proceeds by experimental work to reproduce different rock types and thus to elucidate their origin and explain their structures.

1. Pioneer Investigations.—Though the experiments of H. B. de Saussure (1740–99) on the fusion of granites and porphyries may be said to mark the earliest beginnings of experimental petrology, the era of rock synthesis should be dated from the time of the researches of Sir James Hall (1761–1832) on the fusion of dolerites found in the neighbourhood of Edinburgh. This investigator showed convincingly that crystalline diabase (British dolerite or whinstone) could be fused and consolidated, according to the rate of cooling, either as black glass resembling natural pitchstone or as crystalline aggregates of minerals much like the diabase from which they came. Hall's most famous experiments, however, were conducted with limestones. Powdered chalk, by being heated in gastight gun barrels, was converted into a crystalline mass of calcite, thus supporting the contention of James Hutton that heat and pressure had consolidated limestones and converted them into marbles. A lapse of almost 90 years had occurred before the experiments of Hall were substantiated, when in 1878 the French petrologists F. Fouqué and Auguste Michel Lévy began their extensive researches on the synthesis of minerals and rocks by pyrogenetic methods. They succeeded in producing, by the use of a gas furnace and a nitrogen thermometer, such rocks as porphyry, basalt and diabase, at the same time obtaining the characteristic textures—porphyritic, ophitic, etc.—by modifying the conditions under which the melts were cooled. With the more siliceous or acid rocks their experiments were much less successful. They advanced for the first time in a convincing manner the explanation that for the crystallization of these rocks the gases, never absent in natural rock magmas, were indispensable mineralizing agents (mineralizers).

Later, it became known that the formation of many minerals is facilitated, or can only be accomplished, in the presence of volatile constituents such as water, borates, chlorides, fluorides, etc. Not only do these assist in promoting the fluidity of the liquid and facilitate crystallization, but they form essential constituents of some of the important minerals occurring in acid igneous rocks (micas, tourmaline, topaz, etc.).

Among the pioneers in synthetic petrology may also be mentioned H. E. Sainte-Clair Deville, H. de Sénarmont, P. Berthier, L. Bourgeois, P. G. Hautefeuille, K. Chrustschoff, C. Doelter, J. Morosewicz and J. H. L. Vogt. To Vogt is owed the first comprehensive essay toward bringing the crystallization of igneous rock magmas definitely under the known laws of solution. Beginning a study of a large series of silicate slags, more or less comparable in composition with igneous rocks, he brought together a large body of information throwing light on the order of crystallization, the composition of the eutectics and the lowering of freezing points of the minerals in slag mixtures, these results being directly applied to the elucidation of the crystallization processes in natural magmas.

2. Geophysical Laboratory.—Up to this period the synthetic work, involving as it did the measurement of the melting point of minerals and the succession of crystallization in more or less complex mixtures, though very suggestive, lacked the strictly quantitative element. Experiments were carried out on materials always containing impurities or foreign substances, and the methods adopted for the determination of fixed thermal points such as melting points, inversion points or heat changes were of doubtful precision. In 1904, with the establishment of the Geophysical laboratory at Washington, D.C., synthetic or physicochemical petrology entered upon a new quantitative era. The work of this laboratory was undertaken in order to enter upon a quantitative study of rock formation which should include those minerals and rocks which are geologically important and those which are economically useful, and those formed directly from the magma and those formed by subsequent alteration. The individual problems are in reality problems for physics and physical chemistry; but the delay in attacking them resulted from the fact that the measured relations established by the exact sciences were scarcely of adequate scope to meet the needs of large petrological questions. The great body of physical and physicochemical measurements was confined to a temperature region below 100° C. while processes operating in rocks may have occurred at temperatures up to 1,400° C., an enormous range over which to stretch the application of ordinary methods and one in which the common forms of apparatus not only fail but are themselves threatened with destruction.

The initial work of the Geophysical laboratory was primarily to extend the methods of accurate temperature measurement to include the entire field of rock formation from 0° to 1,600° C. The electric pyrometer reached such precision that an error of one or two degrees is all that need be expected in measuring temperatures up to 1,600° C.; moreover, these temperatures can be maintained quite steady for days or weeks at a time. Calorimetric measurements were improved; specific heats can be determined with great accuracy even at the highest temperatures. At the same time petrographic methods were advanced so that the crystallographic and optical constants of the very minute crystals obtained in silicate melts could be accurately measured. The investigation of mineral substances under high pressures and high temperatures combined, and in the presence of volatile constituents, also became a subject of study.

With these methods of precision available for the study of rock materials, examination of simple mineralogical systems was prosecuted. An understanding of the chemistry of the common oxides of rocks and of their combinations is essential to the progress of petrology. Experimental work was conducted on the combinations of the oxides lime, magnesia, alumina, silica; the six possible binary systems were fully worked out and the four possible ternary systems thoroughly studied, while portions of the quaternary system were successfully explored. These equilibrium studies were further extended by investigations on silicate systems containing ferric and ferrous oxide, soda and potash and by exploration of some important systems containing water. Much light was thereby thrown on the processes taking place during the consolidation of igneous magmas which, though much more complex in their constitution, yet clearly show by petrographic examination closely similar phenomena, such as are revealed in the crystallization behaviour of these simpler systems. The application of these laboratory investigations to the elucidation of the origin and evolution of igneous rock types will be considered hereafter (see *Plutonic Complexes*, below). *See* also Mineralogy: *Experimental Mineralogy.*

III. CLASSIFICATION OF IGNEOUS ROCKS

Igneous rocks are subdivided into many groups according to their composition, chemical and mineralogical, their structures and textures and their mode of occurrence. Between allied rocks there are, however, no hard and fast boundaries, for by increase or decrease in the proportions of their constituent minerals, they pass by every gradation one into the other. Similarly the distinctive textures of one kind of rock may often be traced gradually merging into those of another. Hence the definitions adopted in establishing rock nomenclature merely correspond to more or less arbitrarily selected points in a continuously graduated series. This is frequently urged as a reason for reducing rock classification to its simplest possible terms and using only a few generalized rock designations.

The earliest attempts at the classification of rocks on modern lines are to be found in the works of K. C. von Leonhard (1823) and Alexandre Brongniart (1827). These and other efforts, principally by K. F. Naumann (1850), Bernhard von Cotta (1855) and Justus Roth (1861), while being built on the criteria of composition and structure of rocks, were largely developed from purely macroscopic investigation or ultimate chemical analysis. The pioneer work of H. C. Sorby (1858) in preparing transparent microsections of rocks opened the way for the discovery of the mineral constituents and textures of the finer grained igneous rocks, and rapid advances in the knowledge of the constitution of igneous rocks followed. The classifications of F. Zirkel (1873) and K. H. F. Rosenbusch (1877) were the first products of the application of the new method of petrographic research, and in these mineral constitution was accorded first place as a basis of subdivision. The effect of microscopic study was to stress the importance of mineralogical and textural characters of rocks to the neglect of other characteristics. Rosenbusch in particular, influenced by the contention principally of K. A. Lossen (who urged the significance of the geological relations of igneous rocks, their occurrence and manner of formation), further developed his classification to express the relationship of geological occurrence and texture, and introduced in the second edition of his *Mikroskopische Physiographie* a fundamental change.

This classification is based first on geological position, then on texture and finally on mineral and chemical composition. Igneous rocks are divided thus into three great groups: (1) deep-seated rocks; (2) dike rocks; and (3) effusive rocks. Like others before it, this classification is still essentially qualitative, and at mid-20th century was the one most commonly adopted by petrographers. An exposition of Rosenbusch's classification is set forth in his *Elemente der Gesteinslehre*, revised by A. Osann (1923).

IV. HABIT OF IGNEOUS ROCKS

Igneous rocks occur essentially in two different ways; *i.e.*, either as lavas or as intrusions.

1. Lavas or Effusive Types.—The lavas have been poured out at the surface and have consolidated after ejection, under conditions which are fairly well understood, seeing that they may be examined at active volcanoes in many parts of the world; the intrusive rocks, on the other hand, have been injected from below into cracks and fissures in the strata and have cooled there beneath masses which conceal them from view until exposed by denudation at a subsequent period. The members of these two groups differ from one another in many respects, so that it is often possible to assign a rock to the one group or to the other on mere superficial inspection. The lavas (or effusive rocks), having cooled rapidly in contact with the air, are as a rule finely crystalline or have at least a fine-grained groundmass representing that part of the viscous semicrystalline lava flow which was still liquid at the moment of eruption. At this time they were exposed only to atmospheric pressure, and the steam and other gases, which they contained in great quantity, were free to escape. Many important modifications arise from this, the most striking being the frequent presence of numerous steam cavities (vesicular structure) often drawn out to elongated shapes subsequently filled up with minerals by infiltration (amygdaloidal structure). As crystallization was going on while the mass was still creeping forward over the surface of the earth, the latest formed minerals (in the groundmass) are commonly arranged in subparallel winding lines following the direction of movement, and the larger early minerals which had previously crystallized may show the same arrangement. The first generation of crystals generally forms before the lava has emerged to the surface, that is to say, during the ascent from the subterranean depths to the crater of the volcano. It has frequently been verified by observation that freshly emitted lavas contain large crystals borne along in a molten, liquid mass. The large, well-formed, early crystals are generally admitted to be porphyritic; the smaller crystals of the surrounding matrix or groundmass belong to the posteffusion stage. More rarely lavas are completely fused at the moment of ejection; they may then cool to form a nonporphyritic, finely crystalline rock, or if more rapidly chilled may in large part be noncrystalline rock, or glassy (vitreous rocks such as obsidian, tachylyte, pitchstone). A common and easily recognized feature of glassy rocks is the presence of rounded bodies (spherulites: Gr. *sphaira*, "ball") consisting of fine divergent fibres radiating from a centre; these divergent fibres consist of imperfect crystals of feldspar, mixed with quartz or tridymite; similar bodies are often produced artificially in glasses which are allowed to cool slowly. Rarely these spherulites are hollow or consist of concentric shells with spaces between (lithophysae: Gr. *lithos*, "stone"; *physa*, "bellows"). Perlitic structure, which is also found to be common in glasses, consists in the presence of concentric rounded cracks as a result of contraction on cooling (*see* PERLITE; SPHERULITE).

The phenocrysts (Gr. *phainein*, "to show"; *krystallon*, "a crystal") or porphyritic minerals are not only larger than those of the groundmass; as the matrix was still liquid when they formed they were free to take perfect crystalline shapes, not being interfered with by the pressure of adjacent crystals. They seem to have grown rapidly, as they are often filled with inclusions of glassy or finely crystalline material like the material of the groundmass. Microscopic examination of the phenocrysts often reveals that they have had a complex history. Very frequently they show successive layers of different composition, indicated by variations in colour or other optical properties; thus augite may be green at the centre and various shades of brown outside this; or it may be pale green centrally and darker green with strong pleochroism (aegirite) at the periphery. In the feldspars the centre is usually more basic and richer in lime than the surrounding faces, and successive zones may often be noted, each less basic than those which lie within it. Phenocrysts of quartz (and of other minerals), instead of sharp, perfect crystalline faces, may show rounded corroded surfaces, with the points of the crystals blunted, and irregular tonguelike projections of the matrix into the substance of the crystal; it is clear that after the mineral had crystallized it was partly again dissolved or corroded at some period before the matrix solidified. Corroded phenocrysts of biotite and hornblende are very common in some lavas; they are surrounded by black rims of magnetite mixed with pale green augite. The hornblende or biotite substance has proved unstable at a certain stage of consolidation and has been replaced by a pseudomorph of augite and magnetite which may be partially or completely substituted for the original crystal but still retains its characteristic outlines.

2. Plutonic or Abyssal Types.—The characteristics of a typical deep-seated rock similar to granite or diorite will now be considered. That these are clearly igneous is proved by the manner in which they have burst through the superincumbent strata, filling the cracks with ramifying veins; that they were at a very high temperature is equally clear from the changes which they have induced in the rocks in contact with them. But as their heat could dissipate only very slowly, because of the masses which covered them, complete crystallization has taken place and no vitreous, rapidly chilled matter is present. As they have had time to come to rest before crystallizing they are not fluidal. Their contained gases have not been able to escape through the thick layer of strata beneath which they were injected, and may often be observed occupying cavities in the minerals; they have also occa-

sioned many important modifications in the crystallization of the rocks. Because their crystals are of approximately equal size, these rocks are said to be granular; there is typically no distinction between a first generation of large well-shaped crystals and a fine-grained groundmass. Their minerals have formed, however, in a definite order, and each has had a period of crystallization which may be very distinct or may have coincided with or overlapped the period of formation of some of the other ingredients. The earlier have originated at a time when most of the rock was still liquid and are more or less perfect; the later are less regular in shape because they were compelled to occupy the interspaces left between the already formed crystals which pressed on them. The former are said to be idiomorphic (*i.e.*, having their own characteristic form, Gr. *idios*, "one's own"), the latter are allotriomorphic (Gr. *hallotrios*, "belonging to another"). There are also many other characteristics which serve to distinguish the members of these two groups. Orthoclase, or microcline, for example, is the typical feldspar of granite, while its modification, sanidine, occurs in lavas of similar composition; leucite is common in lavas, very rare in plutonic rocks; muscovite is confined to the intrusives. These differences show the influence of the physical conditions under which consolidation takes place. Fundamental studies on the thermal behaviour and polymorphism of the group of minerals and on the variable inversion temperature of rock-forming quartz shed new light on the long-known mineralogical differences between feldspars and quartz found in acid volcanic rocks and the same minerals found in plutonic rocks. The differences were interpreted as due to changes brought about in these constituents of the plutonic rocks during cooling by processes of inversion, unmixing and recrystallization from an initial character similar to that of the feldspars and quartz of the corresponding volcanic rocks. These conclusions necessitate some revision of ideas of "order of crystallization" and of the origin of mineral textures in deep-seated igneous rocks of this mineralogical character (*J. Geol.*, vol. 58, pp. 489–511 [1950]; vol. 60, pp. 107–124 [1952]). (*See* FELDSPAR.)

3. Intrusive or Hypabyssal Types.—There is a certain class of intrusive rocks which have risen upward toward the surface but have failed to reach it, and have solidified in fissures as dikes and intrusive sills at no great depth. To this type the name hypabyssal is often given in distinction from the plutonic (or abyssal) which formed at greater depths. As might be expected, the hypabyssals show structures intermediate between those of the effusive and the plutonic rocks. They are very commonly porphyritic, not rarely vitreous and sometimes even vesicular. In fact many of them are indistinguishable petrologically from lavas of similar composition. The attempt to form a special group of hypabyssal (intrusive and dike) rocks has met with much criticism and opposition. Such a group certainly cannot rank as equally important and equally well characterized with the plutonic and the effusive. But there are many kinds of rock which are not found to occur normally in any other manner. As examples the lamprophyres, the aplites and the porphyries might be cited. These never occur as lava flows or as great plutonic bosses; if magmas of the same composition as these rocks occur in either of these ways they consolidate with different assemblages of minerals or different structures.

In subdividing the plutonic, the hypabyssal and the effusive rocks, the principle is followed of grouping those together which resemble one another in mineral constitution and in chemical composition. In a broad sense these two properties are interdependent.

V. CHEMICAL CHARACTERS

1. Rock Elements.—Twelve elements (oxygen, silicon, aluminum, iron, calcium, sodium, potassium, magnesium, titanium, phosphorus, hydrogen and manganese) constitute about 99.6% of the earth's crust. Of these oxygen is the most abundant and constitutes 46.59% of the igneous rocks of the crust, the elements given above being placed in their order of abundance. These petrogenic or rock elements occur typically as oxides, simple silicates, aluminates, fluorides, chlorides and sulfides. In rock analyses they are stated as oxides. From a computation based on 5,159 analyses, H. S. Washington and F. W. Clarke arrived at the following as the average percentage composition of all igneous rocks: silica, 59.14; alumina, 15.34; ferric oxide, 3.08; ferrous oxide, 3.80; magnesia, 3.49; lime, 5.08; soda, 3.84; potash, 3.13; water, 1.15; titanic oxide, 1.05; phosphorus pentoxide, 0.3; manganous oxide, 0.12; inclusive 0.3. (*See* GEOCHEMISTRY: *Chemistry of the Earth: Abundance and Origin of Elements.*)

2. Range of Composition.—The known igneous rocks show a wide but limited range of composition. As the most abundant and essential rock minerals are either silica or silicates, silica shows the highest maximum and the widest range of these oxides. In some magmatic ores its content falls to zero but it rises to 78% in some acid granites; alumina varies normally between 10% and 20%, and some corundum-bearing rocks contain much more, being probably not of pure magmatic origin; iron oxides have a general range from 15% to less than 1% and magnesia from 25% to less than 1%. In some olivine rocks (dunite) it reaches a value of 48%. Lime is highest in some pyroxenites and anorthosites (20%–22%), but its general range is from 15% to zero. Soda reaches a maximum of 18%–20% in almost pure nephelite rocks (urtite) but has a general range from 15% to nearly zero. Potash usually varies from 10% to zero. Water in fresh crystalline igneous rocks seldom reaches more than 2%, but pitchstones may contain up to 10%.

3. Common Minerals and Associations.—The commonest minerals of igneous rocks are the feldspars, pyroxenes and amphiboles, quartz and the micas. From a statistical examination of 700 igneous rocks an average composition has been calculated as follows: feldspars 59.5%, pyroxenes and amphiboles 16.8%, quartz 12.0%, micas 3.8%, other minerals 7.9% (apatite 0.6%, titanium minerals 1.5%). This is clearly only an approximation. Rock minerals have been classified empirically into two groups, according as they are capable or incapable of existing in the presence of free silica; *i.e.*, into saturated and unsaturated minerals. The former group includes such minerals as the feldspars, pyroxenes, amphiboles and micas; and the latter olivine, nephelite, leucite and other feldspathoid minerals.

Certain minerals are as a matter of common observation not found together in igneous rocks. Olivine (except fayalite) and quartz do not occur in association, but are represented by rhombic pyroxene. The associations nephelite and quartz, leucite and quartz, pyroxenes or amphiboles and muscovite are almost unknown among magmatic crystallizations; on the other hand, certain mineral associations or parageneses occur frequently; thus aegirite (acmite) and arfvedsonite, nephelite and noselite, common hornblende and titanite are well known as faithful companions in igneous rocks. Again some minerals are restricted to particular magmas; melanite, melilite and certain rare zirconium-titanium minerals are almost entirely confined to the alkali igneous rocks. By inspection of a rock analysis it is frequently possible to state approximately what minerals the rock will contain, but there are numerous exceptions to any rule which can be laid down. The minerals which crystallize from an igneous magma may depend largely on the physical conditions under which the liquid consolidates; accordingly, rocks of almost identical chemical composition but with widely different mineralogical constitution are found. Such rocks, as already noted, are referred to as heteromorphous. Some familiar examples of assemblages of this character are mica syenite and leucite basalt, minette and leucite basalt, hornblendite and websterite.

Certain minerals are practically confined to deep-seated rocks, *e.g.*, microcline, muscovite, diallage and almandine garnet; on the other hand, leucite is very rare in plutonic rocks, as is also anorthoclase and the variety of potash feldspar known as sanidine. Some of these peculiarities are readily explicable, as they depend on the pressure, temperature or concentration of volatile constituents in the crystallizing magma. Others still represent a problem for solution. The subject will be referred to again in a later part of this article.

4. Acid, Basic and Alkali Rocks.—In the classification generally adopted by petrographers, the silica content of the magma

TABLE I.—*Alkali Rocks Containing Nephelite and Leucite*

Commonest minerals	Alkali feldspar Nephelite or leucite Augite Hornblende Biotite	Plagioclase (lime soda) Nephelite or leucite Augite Hornblende (olivine)	Nephelite or leucite Augite Hornblende (olivine)
Plutonic . . .	Nepbelite-syenite Leucite syenite	Essexite Theralite	Ijolite Urtite Missourite
Hypabyssal . .	Nephelite-syenite —porphyry Tinguaite	Essexite and Theralite } Diabase	Nepbelite dolerite
Volcanic . . .	Phonolite Leucitophyre	Tephrite Basanite	Nephelite basalt Nephelinite Leucite basalt

forms a basis of further subdivision of igneous rocks. The division of volcanic rocks into acid, intermediate and basic was devised in the first place by W. H. Abich (1841). When this division is applied to igneous rocks in general, those which contain most silica and which if crystallized yield free silica as quartz are erected into a group designated the acid rocks in allusion to the assumed role of silica in the mineral kingdom. Those which have low silica percentages and are rich in magnesia, lime and iron—so that quartz is absent while olivine, pyroxene or calcic feldspar are usually abundant—form the basic group. The intermediate rocks include those characterized by the general absence of both quartz and olivine.

An important subdivision of the intermediate as well as the basic group contains a very high percentage of alkalies (soda or potash or both), and consequently has minerals such as nephelite, noselite, analcite or leucite, minerals not common in other rocks. This group is often referred to as the alkali rocks. Lastly, members of a small subgroup rich in olivine (peridotite, dunite), pyroxene (pyroxenite) or calcic feldspar (anorthosite) have been called the ultrabasic rocks. They have low percentages of silica but much iron, magnesia or lime. With the exception of the last group, including also such ultrabasic lavas as augitite and limburgite and a few related rocks such as monchiquite, melilite basalt and alnöite, practically all igneous rocks contain feldspar or feldspathoid minerals. In the acid rocks the common feldspars are orthoclase, with perthite, microcline and oligoclase, all having much silica and alkalies. In the basic rocks labradorite, bytownite and anorthite prevail, being rich in lime and poor in silica, potash and soda. Augite and olivine are the common ferromagnesian minerals of the basic rocks, but hornblende and biotite are on the whole more frequent in the acid rocks.

5. Mineralogical Constitution.—The classification in Tables I and II is based essentially on the mineralogical constitution of the three great groups of igneous rocks. The alkali rocks containing nephelite and leucite are treated separately, for, though they show transitions into the corresponding intermediate and basic rocks (syenites, diorites, gabbros, etc.), they contain many minerals which are unknown in other rocks. In a purely formal classification such as is outlined here they are more conveniently considered as a distinct series. Their genetic relations among themselves and with the other rock types are considered later.

The lamprophyres form a peculiar group of hypabyssal rocks not included in the tables. They usually occur as dikes in association with granites, syenites, diorites and gabbros, and are basic differentiates of these parent rocks. Thus the minettes, vogesites and kersantites (*see* LAMPROPHYRE) occur in association with granitic or quartz diorite masses, while camptonites, monchiquites and alnöites may be found commonly as satellites of alkali plutonic masses like nephelite-syenite or essexite.

The classificatory scheme here adopted is admittedly artificial, for it subdivides rocks without particular reference to their genetic relationships. Even regarded as a classification for a utilitarian end it has many imperfections; the subdivisions are of unequal value and transitional types are not included. The latter, however, can be accommodated by further subdivision. Many of them have received special names. The quartz syenites may be interposed between granite and syenite, the tonalites between granite and diorite and so on.

The question may be asked: When is a rock entitled to be recognized as belonging to a distinct species or variety and deserving a name for itself? It must, first of all, be proved to occur in considerable quantity at some locality or, better still, at a series of localities, or to have been produced from different magmas at more than one period of the earth's history. In other words, it must not be a mere anomaly. Moreover, it should have a distinctive mineral constitution, differing from that of other rocks, or something individual in the characters of its minerals or of its structures. It is often surprising how peculiar types of rock, believed at first to be unique, turn up with identical features in widely scattered regions; alnöite, for example, occurs in Norway, Scotland, Quebec, British Columbia, New York and Brazil, tinguaite in Scotland, Norway, Brazil, Montana, Portugal, etc. This indicates that underlying all the variations in mineralogical, structural and chemical properties there are definite relationships which tend to repeat themselves, producing the same types whenever the same conditions are present.

6. Quantitative Classifications.—Various attempts have been made to introduce a quantitative element into igneous rock classification. These have followed either chemical or mineralogical lines. The principal of these is the quantitative chemical classification introduced by a group of U.S. petrographers. The chemical composition of an igneous rock is here regarded as its fundamental characteristic and a series of subdivisions is erected on this basis. Other criteria are relegated to the background. The completed rock analysis is first interpreted in terms of an ideal set of minerals which constitutes the norm, but which in reality seldom corresponds to the actual composition (mode). The rocks are then divided into groups strictly according to the relative proportions of these ideal minerals to one another. The details of the classification need not be described here as they are fully set forth in W. Cross, J. P. Iddings, *et al., Quantitative Classification of Igneous Rocks* (1903).

A quantitative element is introduced in other systems by subdividing rocks into groups by arbitrary lines based on mineral percentages: a complicated system framed on these lines was devised by A. Johannsen (*J. Geol.*, 1917, 1919). In another the prime divisions are erected on so-called "principle of silica-saturation" (S. J. Shand, *Eruptive Rocks* [1947]), while a third combines some of the features of both the quantitative chemical classification and the Johannsen system with the larger groups of the Rosenbusch system (P. Niggli, *Schweiz. Min. Petrogr. Mitt.* [1931]). In all, the effect of the introduction of the quantitative element has been to increase the artificiality of the system and by this means to obscure the genetic relations existing between rock types. For this reason these systems are unlikely to supplant

TABLE II.—*Acid and Basic Rocks*

	Acid	Intermediate		Basic	Ultrabasic
Commonest minerals	Quartz Orthoclase (and oligoclase) Mica Hornblende Augite	Little or no quartz		No quartz	Augite Hornblende Olivine (basic plagioclase)
		Orthoclase Hornblende Augite Biotite	Plagioclase Hornblende Augite Biotite	Plagioclase Augite Hypersthene Olivine	
Plutonic	Granite	Syenite	Diorite	Gabbro Norite	Peridotite Pyroxenite Hornblendite (anorthosite)
Hypabyssal	Quartz porphyry	Orthoclase Porphyry Orthophyre	Porphyrite	Diabase	Picrite
Volcanic	Rhyolite Obsidian	Trachyte	Andesite Dacite	Basalt Tachylyte	Limburgite Augitite

the qualitative classification in general use. It is indeed largely to the influence of "quantitative classifications" that the bewildering and unnecessary multiplicity of igneous rock names must be ascribed.

VI. PETROGRAPHICAL PROVINCES

As long ago as 1872 H. Vogelsang had noted that the igneous rocks of certain districts possessed textural or mineral characters in common, serving to distinguish them from the rocks of other districts. The researches of J. W. Judd (1886) and J. P. Iddings (1892) further substantiated this observation and showed that this community of petrographic character applied to the igneous rocks erupted or intruded during a particular period of igneous activity within the region. To such regions Judd gave the name petrographical provinces and Iddings employed the term consanguinity to express the genetic relationship implied in these resemblances among associated rocks. Excellent examples of such petrographical provinces or comagmatic regions, as they were termed by H. S. Washington, are the Oslo region of southern Norway, characterized by Permian alkali intrusions and extrusions; the Roman region, characterized by rocks rich in potash; the alkali province of central Montana; and the Tertiary calc-alkali province of Hungary. On a larger scale the volcanoes which girdle the Pacific (Andes, Cordillera, Japan, Philippines, etc.) and those which occur on the volcanic islands of the Atlantic illustrate the same phenomena. The consanguinity in the igneous series of a petrographical province implies that the whole assemblage is derived from some common deep-seated magma, during a period which, while necessarily prolonged, was not of vast duration in a geological sense. The assemblages of a province may and often do show a wide diversity of rock type embracing intrusions and extrusions.

Prolonged eruptions have in a few cases resulted in provinces of a somewhat monotonous character as a result of the predominance of one kind of rock. Thus the lavas of the Hawaiian Islands are mostly basaltic, as are those of Oregon, Washington and the Deccan, India, all of which form geological masses of enormous magnitude. In the Oslo district, on the other hand, the assemblages comprise (among the intrusive rocks) a wide range of type—hornblendite, essexite, larvikite, lardalite, nordmarkite, soda and potash granites.

A. Differentiation

The process by which a magma is split into a variety of partial products is known as differentiation. Its importance from the standpoint of theoretical petrology is very great; it is, in point of fact, the fundamental problem of petrogenesis. The differentiation may appear as a variation either in a single rock body or in an associated series of separate intrusions or extrusions. In the first case a single intrusion shows variation in different parts of its mass, the extreme varieties being usually connected by gradual transition. The contrasted parts are frequently arranged symmetrically with reference to the borders of the mass, forming concentric zones in bosses or laccoliths suggestive of a differentiation *in situ* connected with the cooling of the mass. Excellent examples of variation of this kind are provided by the laccolithic intrusions of the Highwood mountains of Montana. The best-known of these—the Shonkin Sag laccolith—has a chilled edge phase, a leucite basalt porphyry (or mafic phonolite) representing a quenched sample of the intruded magma, followed inward by a thick zone of shonkinite which forms an envelope to a central horizontal layer of alkali syenite.

Variation in an associated series is exemplified by the succession of lavas emitted from a volcanic focus. These may differ considerably from one another. Thus in the Berkeley hills near San Francisco, Calif., the volcanic succession is a repeated series of andesites, basalts and rhyolites. In other cases the lavas emitted are much more varied and, while no significant relations in the succession can be discerned, it is to be remembered that a significant order may be obscured by the overlapping of the flows from nearby volcanoes. In the simpler cases the order of eruption is one of increasing divergence from an initial type.

B. Plutonic Complexes

A series of plutonic rocks intimately associated and localized at a centre constitutes a plutonic complex. Such complexes often contain a great diversity of petrographical types ranging from peridotite and gabbro through diorite to acid granite. The succession of these intrusions follows an order of decreasing basicity, the later and more acid rocks usually occupying the greater part of the complex, the earlier and more basic being subordinate in amount and restricted to the borders of the mass. Excellent examples of such plutonic complexes are provided by the early Devonian instrusions of newer granites of the Scottish Highlands (*e.g.*, Garabal hill, Loch Lomond). What are the operative factors which led to differentiation?

1. Unmixing.—The possible processes leading to heterogeneity in a magma may be considered under (1) those occurring in the liquid prior to crystallization (liquid $\leftrightarrows$ liquid equilibrium); and (2) those incident on crystallization (crystal $\rightleftarrows$ liquid equilibrium). In the first group comes the process known as liquation or unmixing. Many liquids, homogeneous at high temperatures, separate with falling temperature into two or more nonconsolute fractions, and the hypothesis that igneous magmas form such immiscible fractions has been favoured by some petrologists, notably Rosenbusch, H. Bäckström and R. A. Daly. From his own studies Vogt concluded that the rock-forming silicates are freely miscible. The only known case among magmas for which immiscibility can be claimed is that of sulfide-containing silicate melts. Such a magma unmixes at a temperature above the region of crystallization of the usual sulfides, and liquid sulfides, especially those of iron, are separated as liquid drops. These, because of their greater density, sink to the floor of the magma, collecting as a distinct sulfide layer or, in some cases, the liquid layer may be injected into the surrounding rocks. These sulfide aggregates form important ore deposits (*q.v.*). It is among lavas which as a group show the various stages of quenching of liquid magmas that the evidence for immiscibility might be expected; the absence of lavas containing glassy globules of composition distinct from that of the main mass of lava goes far to show that immiscibility is not an operating factor in petrogenesis.

Experimental evidence of immiscibility in silicate liquids was indeed obtained, but the composition range of liquids which show it is unlike that exemplified by rock magmas. This limited miscibility is found in mixtures of silica with any of the oxides (lime, magnesia, ferrous oxide, alumina), but in a region of very high silica content. The minimum temperature for the existence of two liquids is in each case only a little below the melting point of silica, or in the vicinity of 1,700° C. The oxides (soda, potash, alumina) show no such immiscible region in their silica mixtures, and moreover it requires only a small proportion of any of these miscible oxides to render miscible with silica the oxides which are themselves immiscible with silica. No natural magmas are known which approximate in composition to the region of immiscibility in these melts. It is true that natural magmas contain, in addition, water, but accumulating experimental studies in hydrothermal systems had up to the 1960s given no reason to believe that fields of immiscibility extend into the composition region of natural magmatic systems.

2. Fractional Crystallization.—The second group of processes referred to above involves a crystal $\rightleftarrows$ liquid equilibrium and comprises crystallization and its converse, the assimilation of crystalline material. Knowledge of the crystallization of silicate magmas is derived from long-sustained observations of igneous rocks themselves and was greatly augmented by high-temperature experimental research on silicate melts. The great body of evidence thus accruing leads to the belief that fractional crystallization is to be recognized as a fundamental process in igneous rock differentiation—the derivation of igneous rocks of diverse but related character. Either the localization of crystallization or the localized aggregation of crystals is sufficient to produce heterogeneity in a rock magma. The first phenomenon, the localization of crystallization, was at one time thought competent to explain those cases of differentiation *in situ* exemplified by the basic marginal phases of intrusive masses. Examination of igneous rocks

early showed that minerals crystallize in a more or less definite order. In general, olivine, hypersthene and other minerals prominent in ultrabasic rocks are among the earliest minerals to separate; then follow augite, calcic plagioclase, hornblende, biotite, potash feldspar and quartz, plagioclase continuing to separate and becoming at the same time more sodic. This is the so-called normal order of crystallization, the validity of which, despite exceptions, has long been recognized. When the rule is expressed in this way the more basic minerals precede the less basic: in a somewhat modified form it was early known as Rosenbusch's law of decreasing basicity. Accordingly, it was supposed that at a cooling boundary there is a precipitation of minerals of early crystallization (basic minerals), the continued growth of many crystals being maintained by diffusion. The completion of this process results in a crystalline mass with a border phase enriched in the minerals of early crystallization.

The rate of diffusion in silicate melts has been the subject of laboratory study and the results obtained show that the possible effects are incompetent to account for the formation of border phases about large intrusions. The marginal phase indeed appears to represent rather a chilled phase having a composition close to that of the original magma, the more acid phase which it enclosed representing a differentiate formed by much slower cooling of the remainder of the magma. The relative movement of crystals with respect to the liquid from which they separated may be of two kinds: (1) movement under the influence of gravity—sinking or floating of crystals; and (2) movement by straining off or squeezing out of residual liquid by earth movement. Both of these processes can be invoked to explain the more important case of differentiation exemplified by an associated series of intrusions or extrusions. In a crystallizing magma (provided viscosity does not inhibit the free movement of crystalline material) as the first formed crystals are denser than the molten material in which they form, they should sink under the influence of gravity in the liquid. The lower regions of the rock mass into which the crystals sink become enriched, the upper regions impoverished, in the constituents of which they are formed. The sinking of crystals in silicate melts has been both experimentally verified in the laboratory and observed in nature. Darwin (1844) suggested that this process was a potent factor in producing diverse rock types. If the evidence of consolidated rock masses themselves be taken, intrusions are found in which such gravitational segregation is indubitably exemplified. Thus the concentration of early formed olivine crystals near the base of sheet- or sill-like intrusions has been observed in the case of the quartz-dolerite sill of the Palisades (Hudson river) and of the picrite-crinanite sill of the Shiant Isles (western Scotland). The Permian picrite-teschenite sills of central Scotland, while exhibiting similar phenomena of settling of olivine in place, provide, in the main, evidence of injection of crystal-charged magma of picrite following closely upon intrusion of a more liquid teschenite which now margins the sills. The role of fractional crystallization in the production of a series of related rock types within a great magma chamber is spectacularly illustrated in some of the largest intrusive complexes laid bare by erosion. These complexes occur at widely scattered localities in the world in the form of sheets of basic igneous rock of great thickness, showing a layered (banded) structure with systematic types of variation within them. Such are the intrusions of the Bushveld, Transvaal; Duluth, Minn.; Sierra Leone, west Africa; Stillwater, Mont.; and Skaergaard, east Greenland—stratiform structures often several miles thick which, despite much diversity in detail, show broad features of similarity in that systematic variation observed within them.

The interpretation of the petrologic structure of these sheets usually assumed either (1) that the complex is the result of successive sheet intrusions varying in composition; or (2) that they represent the product of crystallization of a single body of magma with gravitative sorting. Detailed examination of the Skaergaard mass made clear that this layered structure arose from fractional crystallization of a magma occupying a deep inverted cone chamber, solidification proceeding from the base upward, the solid phases accumulating like a sediment on the floor. The intrusion consists of basic rocks and comprises a marginal rock group and a central layered group. The marginal rocks show fluxion structures and banding parallel to the steeply dipping contacts. The layered group is exposed to a thickness of three kilometres, the whole of this consisting essentially of plagioclase, olivine and pyroxene, their composition as solid solution series changing gradually from the lower to the upper horizons. At the lower horizons the plagioclase is bytownite, in the upper it is an andesine-oligoclase. Olivine in the lower horizons is poor in iron, but at the top of the series is fayalite, and the pyroxenes show similar enrichment in iron in their phases as they are traced upward.

The separation of the rocks of the intrusion into marginal and layered groups and the differentiation of the latter may be explained by the fact that the liquid magma was sufficiently mobile to allow a convective circulation and equilibrium, the temperature gradient attained, however, being much less than the downward increase in the average crystallizing temperature, because of the increasing hydrostatic pressure (freezing-point gradient). Data which are available for the silicates give the approximate magnitude of these effects as $\frac{1}{2}$° C. per kilometre for the convective gradient and 3° C. for the freezing-point gradient. Accordingly, although cooling would take place from the top and flanks of the intrusion and the temperature at these points would be cooler, the solid phases would separate near or at the bottom and would gradually accumulate on the floor.

In the Skaergaard mass only the upper portions of the intrusion are laid bare, the rock types ranging from hypersthene olivine gabbros to ferrogabbros and fayalite ferrogabbros with a final residual granophyric differentiate close to the roof. The remarkable correlation in detail of the composition of crystals of solid solution series with their position in the layered mass and the ordered sequence of rock product so yielded, present in all a convincing picture of the results of fractional crystallization of a once homogeneous magma. It is not unlikely that the mechanism thus clearly made manifest for the Skaergaard intrusion characterizes other layered sheets (*e.g.*, Stillwater), although the history of some of these may be further complicated and its tracing blurred by the intervention of intimately associated intrusions.

3. Application of Laboratory Investigations.—The trend in mineral composition revealed in layered series of rocks such as that already described is illuminated by experimental laboratory study of phase equilibriums in silicate systems of related composition. The main contributions in such synthetic studies have come from the Geophysical laboratory at Washington, D.C. (see *Rock Synthesis,* above). Systems which approach in their complexity some of the simpler types of igneous rocks were explored, and the results obtained justify the conclusion that the fusion and solidification phenomena of igneous rocks are capable of systematic treatment. Starting with pure chemical substances, the melting points, dissociation temperatures and inversion points of numerous rock-forming minerals were determined and the equilibrium phenomena of two- and three-component systems involving the commoner oxides of igneous rocks were quantitatively elucidated.

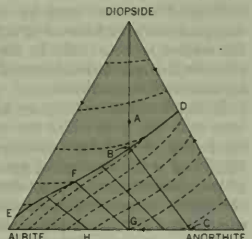
This study embraced the binary and some of the ternary systems of the oxides lime, magnesia, ferrous oxide, alumina, soda, potash and corundum with silica, and was extended to the exploration of certain plane sections of four- and five-component systems. The investigation of mineral inversions provided data throwing light on the temperature of igneous magma. Such of these inversions as are enantiotropic, or reversible, and take place without appreciable lag can be appropriately used as geological thermometers.

The study of binary and more complex systems has shown that the eutectic relation—for so long given a pre-eminent role in discussions of the crystallization of igneous rocks—is but one of several relations that may obtain between two or more components. Crystallization processes are normally complicated by solid solution and incongruent melting. The former phenomenon is widespread, for most of the major constituents of igneous rocks—feldspars, pyroxenes, olivines, amphiboles and micas—are members of complex solid solution series. (*See* MINERALOGY: *Nature of Minerals: Solid Solution.*)

In systems of three components the crystallization phenomena are often complex: occurrence of inversion points in one or more of the components, the formation of binary or ternary compounds with congruent or incongruent melting, and the formation of isomorphous mixtures, limited or unlimited, among the phases, are some of the many complications met with in the silicate systems investigated. Ternary systems that have been studied include those mixtures from which the phases plagioclase, pyroxene, olivine, silica and the alkali alumina silicates, potash-soda feldspars, leucite and nephelite, are precipitated.

The crystallization phenomena in a system involving the first two of the phases indicated above—diopside-albite-anorthite—may be taken as an example. The equilibrium diagram is shown in the accompanying figure. The crystallizing phases are diopside and plagioclase. These mixtures are therefore comparable with simple basaltic or gabbroic magmas on the one hand and simple dioritic (augitediorite) magmas on the other, according to the nature of the plagioclase.

Consider the crystallization of a liquid whose composition is represented by the point A (50% diopside, 50% plagioclase—Ab_1An_1). Crystallization begins with a separation of diopside (supposed to be a simple mineral and not an isomorphous mixture, as it would usually be in rocks) at about 1,275° C. At 1,235° C. the excess of diopside (B) has separated out, and feldspar begins to crystallize. It has about 80% anorthite (C). Thereafter diopside and feldspar both crystallize, but as the composition of the liquid travels along the line DBE from B to F the composition of the feldspar changes from C to G (if it is supposed that all the early feldspar which is unduly rich in anorthite is stage by stage resorbed). The resulting rock has the mineral composition above stated; but if resorption of feldspar is incomplete the last-formed feldspar is richer in albite and has a composition H. The feldspar crystals in that case are zonal with basic centres. If at any time crystallization is suddenly brought to an end a glassy groundmass will be formed, which is richer in soda and silica than the original magma and contains zoned feldspar crystals. This is exceedingly like what takes place in many basaltic lavas. Again, if the original mixture had been richer in feldspar, so that the composition point lay below the line DE, feldspar would have crystallized out first. Original compositions near B then yield early both diopside and plagioclase phases and quenching at this stage would show both enveloped in a glassy base. This is in keeping with observations on glassy basalts which exhibit plagioclase and pyroxene of early crystallization set in preponderant glass.



EQUILIBRIUM DIAGRAM OF CRYSTALLIZATION PHENOMENA

The separation of liquid from crystals can be accomplished not only by zoning but also by the sinking of crystals from the upper layers of the liquid. The resulting liquid is enriched in albite and, under favourable circumstances, the final liquid may approach the albite-diopside eutectic of composition 97% Ab, 3% diopside. The analogy with the differentiation course of gabbroic magma is clear. A mixture rich in diopside and anorthite-rich plagioclase, corresponding to an anorthite-rich gabbro or eucrite, may pass to an assemblage rich in more acid plagioclase with subordinate diopside, corresponding to an augite-diorite.

4. Discontinuous-Reaction Series.—The continuous-reaction relation between crystals and liquid in the systems just studied is of fundamental importance in the crystallization history of magmas. This reaction is common to all solid solution series, and such solid solutions are called continuous-reaction series. Very similar effects, however, are produced by another type of crystallization phenomenon revealed in synthetic melts. In this case an early precipitated phase reacts at a certain temperature with the surrounding liquid and a new phase is precipitated, a reaction process of a discontinuous kind. This reaction is illustrated in the system forsterite (olivine)-silica. Here there are three solid phases, forsterite, protoenstatite ($MgSiO_3$) and cristobalite (SiO_2). The orthorhombic pyroxene, protoenstatite, has an incongruent melting point and dissociates at 1,557° C. into forsterite and liquid. From all melts of composition between Mg_2SiO_4 and $MgSiO_3$, the first phase to crystallize is forsterite, which continues to separate until the temperature of 1,557° C. is reached, when the olivine reacts with the liquid to form protoenstatite. When equilibrium is established the resulting crystalline mass consists wholly of olivine and pyroxene. If, however, the opportunity for reaction is inhibited, either by the sinking of olivine crystals or by their enclosure in the reaction product, the course of crystallization is extended and the third phase, silica, is precipitated giving a mass composed of residual olivine, pyroxene and silica.

A reaction relation of this type may effect a series of compounds in a crystallizing melt. These, arranged in their order of succession, constitute a discontinuous-reaction series. The combined effects of discontinuous and continuous reaction are revealed in the related ternary systems diopside-forsterite-silica. Here the magnesia pyroxene forms a complete series of solid solutions (monoclinic pyroxenes) with diopside; they form a continuous-reaction series, the crystals in equilibrium with the liquid being relatively enriched in the magnesian end member ($MgSiO_3$). The effect of hindering the reaction relations is now twofold, the residual liquid (or upper layers of the liquid if sinking of crystals prevails) is enriched in silica and the diopsidic pyroxene, as a result of the offset in composition.

The lowest point of formation of liquid in the system (there is no ternary eutectic) is the binary eutectic diopside-silica. In ternary silicate systems containing ferrous oxide, *e.g.*, in the system MgO-FeO-SiO_2, fractional crystallization effects a concentration of iron in the residual liquid which for some initial compositions may yield, according to the degree of fractionation, crystalline aggregates of ferriferous pyroxene and silica or ultimately iron-rich olivines and silica.

5. Natural Magmas.—That reaction processes of these kinds operate in natural magmas is clearly demonstrated. They are seen among minerals in zoned crystals of solid solutions like the plagioclase feldspars and the complex pyroxene phases, or in the resorbed borders of magnesian olivines with their pyroxenic mantles; their cumulative effects may be revealed in the graded sequences in mineral compositions in a layered intrusion, such as that of Skaergaard, crystallizing upward from its base, or in the association of related but contrasted rock types, whether these be the contrasted parts of gravitationally differentiated sills or the contrasted separate intrusions of a plutonic complex.

The normal calc-alkali magma, more complex in composition than the synthetic melts investigated, contains other components, including water, and from these natural melts mineral phases such as amphiboles and micas with constitutional hydroxyl are precipitated. Petrographic data make it clear that these too take part in the reaction process.

The principal minerals of these igneous rocks can in fact be arranged as reaction series, such that any member is produced from the preceding member by reaction with liquid magma, as already instanced by the reaction pair, olivine-pyroxene. The plagioclase feldspars together with potash feldspar form one series and the olivines, pyroxenes, amphiboles, micas and quartz constitute another. Inspection of this order will reveal that it is in essence the "normal order" already recognized in the rule formulated long ago by Rosenbusch.

A basic magma quickly cooled may give rise simply to basic plagioclase and pyroxene or yield by fractional crystallization a differentiation chain embracing all the minerals enumerated above, the continual offset in composition of the residual liquid in which water accumulates being accomplished by appropriate removal of crystals through gravitative settling, squeezing out or filtering off of interstitial liquid by earth movement during crystallization.

6. Hydrothermal Systems.—The extrapolation of experimental equilibrium studies based on data obtained from anhydrous silicate systems, such as the foregoing, to natural rocks, led to

great advances; nevertheless the evidence that many igneous rocks have crystallized in the presence of water vapour and in fact contain hydrous mineral phases made clear the limited applicability of the experimental results, directly to the interpretation of the crystallization history of the more siliceous and alkaline rock assemblages. Experimental attack on hydrothermal systems followed later and an outline of the scope of these researches is now presented.

Before World War II quantitative phase equilibrium studies in silicate systems containing volatiles, particularly water, had been few. G. W. Morey and C. N. Fenner had worked out the system H_2O-K_2SiO_3-SiO_2 (report, 1917) and at a later date R. W. Goranson had demonstrated the solubility of water in a liquid of granite composition (report, 1931). During and immediately after the war the great interest in certain crystalline phases, especially quartz, had stimulated a great deal of hydrothermal work and radically new equipment was developed. The first systematic study of a silicate system comparable with a natural assemblage—the system MgO-SiO_2-H_2O—was completed in 1949. This study opened a new era of conquest of the wet mineral silicate and in many respects laid the groundwork for much of the later investigations in the hydrothermal field. This work demonstrated that no liquid appeared in the ternary system even at 1,000° C. and at a water vapour pressure of 40,000 lb. per square inch, thus throwing new light on the problem of emplacement of peridotites and serpentines in the upper crust. Most of the postwar hydrothermal studies were in fact carried out under pressure temperature (PT) conditions below that at which a liquid (melt) phase appears and above the critical temperature of water. These studies are therefore largely concerned with crystal $\rightleftarrows$ vapour equilibrium. Examples of such subsolidus studies were those of SiO_2-H_2O, CaO-SiO_2-H_2O, MgO-Al_2O_3-SiO_2-H_2O, and numerous researches dealing with the synthesis and stability of individual mineral groups—feldspars, garnets, micas, amphiboles, nephelite-kalsilite, analcite and several carbonate systems. These investigations proved of particular importance in the study of rock metamorphism (*q.v.*) and some had their application also in the interpretation of phase relations in the cooling history of the igneous rocks.

The most significant liquidus studies related to the petrographically important system of the alkali feldspars ($NaAlSi_3O_8$-$KAlSi_3O_8$) and of these with SiO_2—*see* especially O. F. Tuttle and N. L. Bowen, "Origin of Granite in the Light of Experimental Studies in the system $NaAlSi_3O_8$-$KAlSi_3O_8$-SiO_2," *Mem. Geol. Soc. Amer.*, 74 (1958). These are the systems which approach in composition the great group of natural rocks, the syenites and granites. The outstanding feature of the researches was the evidence found to support the indications that a complete series of solid solutions existed between potash and soda feldspars at elevated temperatures, but that in the subsolidus region a solvus existed with two feldspars existing side by side. Homogeneous synthetic feldspars thus exsolved at lower temperatures in confirmation of the accepted theory of most natural perthites. In the ternary system with silica at high water-vapour pressures the liquidus has a thermal trough near the centre toward which all liquids moved on crystallization.

This minimum had a composition in the range common for granites, a result in harmony with a long-held view of the magmatic origin of this rock type. The investigation of more basic assemblages of simple gabbroic or eucritic composition, *e.g.*, the system diopside-anorthite, under high water pressure revealed a marked lowering of the liquidus and a change in the composition of the binary eutectic, with the implication that water is markedly soluble in gabbroic magma, as had been shown earlier for the granitic liquid system.

7. Magmatic Assimilation.—Heterogeneity in a magma may derive through a crystal liquid equilibrium not only by the spontaneous process of fractional crystallization and reaction but also by reaction of liquid magma with its wall rock or with what foreign inclusions it may incorporate. This process, known as assimilation, may lead to the development of a diversity of rock type and is to be recognized as an important factor in petrogenesis.

It seems probable that the heat effect connected with the solution of solid rock by a liquid magma is always negative, solution being accompanied by absorption of heat, usually of the order of the latent heat of melting. Simple solution would then demand large amounts of heat, which are only available if the liquid possesses great superheat. Intruding magmas, however, can scarcely be at a temperature much above their crystallization range. Such effects of magma upon its enclosures as are observed must therefore be attributed to processes of reaction and precipitation.

The concept of the reaction series finds fruitful application in the study of this problem. Enclosures of rock fragments in a magma may be divided broadly into two classes, those of igneous and those of sedimentary origin. The first class is built normally of minerals which are members of the reaction series. The magma itself, saturated with a given member of such a series, is effectively supersaturated with all earlier members of that series. If the inclusion is built of these earlier members the magma cannot in consequence dissolve them. It can, however, react with them and transform them into the member with which it is saturated, often by passing through other members of the series as intervening steps.

These changes effected by subtraction of material from the magma induce withdrawal precipitation of the phase with which the magma is saturated. In the course of the reaction the inclusion itself is often disintegrated and may come to be completely incorporated in the liquid.

With an inclusion built up of members of the reaction series later than that with which the magma itself is saturated, the process is one of reactive solution—the inclusion becoming part of the liquid at the expense of precipitation of the magma saturated phase. On the liquid, the resultant effect is a pushing onward along the normal course which fractional crystallization in the process of cooling might accomplish. In these reactions no phase foreign to the reaction series is normally precipitated, and there may result locally rock types scarcely distinguishable from types derivable by fractional crystallization. Plutonic complexes with their range of associated intrusions—basic to acid—often show clear evidence of extensive hybridization by reaction of a later (more acid) magma upon an earlier (more basic) consolidated product, the rock types found near the border approximating in composition and structure to a range of igneous rocks of a normal differentiation series while being in fact the result of hybridization brought about by action of liquid (acid) magma upon a basic (gabbroic) rock.

The monzonitic and tonalitic margins of granitic masses of some igneous complexes may be traced to the hybridizing influence of acid magma on an earlier plutonic rock of basic or ultrabasic composition of which all superficial traces may have disappeared. The newer granite complexes of Scotland provide convincing demonstration of hybridizing processes of this nature. The effects of reaction of igneous magmas upon sediments set a more difficult problem, since sedimentary material may not belong to the reaction series.

In many cases the incorporation of sediments in a magma, while yielding adjustments in the composition and relative proportions of existing phases, may effect but little modification in the general course of fractional crystallization. On the other hand, extended incorporation of certain types of sedimentary material may lead to the precipitation of new mineral phases not normally met with in igneous rocks.

Gabbro magma assimilating shales or slates may pass first into norite by precipitation of rhombic pyroxene and basic plagioclase, at the expense of clinopyroxene, and eventually yield cordierite norites. Rocks of this character are well developed in Aberdeen county and elsewhere. Basaltic magma, through assimilation of limestone, may give products rich in melilite and wollastonite and yield, at least locally, an alkali fraction from which nephelite is precipitated. Whether basic magma through this mechanism can generate alkali rocks on a large scale is a question yet to be determined. That their production is not limited to this mechanism, however, is clearly attested by the geological environment and petrographical relations of many examples of this group of rocks.

Assimilation processes clearly play a significant role in the development of some rock assemblages, and among these are to be expected rock types which exhibit in both composition and structure the characteristics of normal igneous rocks. The full contribution of these processes has yet to be evaluated though a limit to their action is prescribed if magmas in general possess little superheat.

8. Palingenesis.—The apparent dominance of granodiorites and granites in orogenic belts led some petrologists to entertain the view that these particular rocks have been derived by remelting of the granitic layer and the intrusion of the resulting liquid to higher levels. This possibility cannot be denied; yet it is to be remembered that a granitic differentiate as a late residual liquid subject to filter pressing during mountain building might well come to dominate in volume the upper regions of a magmatic tract laid bare by erosion. It is conceivable, however, that some granites may have their immediate origin in such refusion and perhaps also that a process of partial refusion may affect siliceous sediments subject to deep burial in the cores of geosynclines. As distinct from the juvenile granites derived by fractional crystallization, granites supposedly originating in this way have been referred to as palingenetic and the process of refusion as palingenesis (Gr. *palin*, "again," *genesis*, "birth"). The genetic link between granitic and basic (basaltic) material remains, for the dominantly mafic character of the crust makes it evident that the sial or granitic layer must ultimately have been derived from such basic material.

9. Granitization.—The aqueous and alkali-bearing residual liquids emanating from granitic magma during its later consolidation stages are known to penetrate into the surrounding rocks. Where these rocks are argillaceous, metasomatism by the alkali solutions acting upon the micaceous minerals of the sediment may result in the feldspathization of such pelitic rocks, transforming them into assemblages analogous in composition to the parent rock from which these solutions came. This is the process of granitization. With such processes there is frequently a merging of the parent intrusive with an igneous-looking rock which is metasomatic in origin.

In the more speculative accounts of the process the parent intrusive itself has been regarded as formed in the same manner and the existence of a genuine igneous intrusive denied, but such an extreme view seems unlikely to be correct. A survey of the problems of granite emplacement with special reference to North America was made by A. F. Buddington (*Bull. Geol. Soc. Amer.*, vol. 70, pp. 671–747 [1959]).

VII. GEOGRAPHIC DISTRIBUTION OF IGNEOUS ROCKS

A study of the geographical distribution of igneous rocks has shown that the earth's surface may be mapped out into more or less definite petrographical provinces, each with its own community of petrographical characters. Strongly contrasted provinces may exist almost side by side, as is seen in the Tertiary Bohemian and Hungarian provinces standing on either side of the Carpathian range, the one characterized by a suite of igneous rocks rich in alkali, the other comprising an assemblage relatively rich in lime, magnesia and iron oxide. The chain of volcanoes that fringes the shores of the Pacific from Tierra del Fuego to Alaska and thence by Japan and the Philippines to Java and Sumatra represents a province of a larger order, characterized by rocks which have so much similarity in many important features that they are certainly of allied origin. These rocks are all of Tertiary and Recent Age; their eruptions began in Eocene or Miocene times and have continued with more or less frequent intermissions up to the present day. The igneous rocks of the Atlantic islands from the Azores to Tristan da Cunha comprise an assemblage of types strikingly different from the igneous rocks of the eastern Pacific borderland. Each of these magmas has been taken as a type, and they are referred to as the Pacific and Atlantic magmas. Chemically the Atlantic (or alkali) rocks are characterized by high percentages of alkalies (potash and soda) in relation to silica and alumina, and mineralogically by the presence of alkali minerals, especially feldspathoids (nephelite, sodalite, analcite, etc.). The Pacific (subalkali or calcic) rocks, on the other hand, show relatively more abundant lime, magnesia and iron oxides.

Certain suites of rocks characterized by high potash content and, mineralogically, by the presence of leucite or abundant potash feldspar and micas, have been separated from the Atlantic suite, though they are perhaps not of co-ordinate importance. Rocks of this character are illustrated by the Quaternary province of the Roman region; Vesuvius belongs to a line of volcanoes (extending from Lake Bolsena to the Campi Flegrei, or Phlegraean fields) that have poured out lavas of this character. They are sometimes known as the Mediterranean suite.

When one turns to the igneous rocks of older geological periods the same contrasted suites can be recognized. The midland valley of Scotland has been the theatre of igneous action both in Lower Devonian and Carboniferous times. The igneous assemblages of the two periods show, however, a striking contrast. The earlier lavas are distinctly of the Pacific type, including andesites, basalts and rhyolites, while the Carboniferous extrusions and dike rocks include trachytes, teschenites, picrites and monchiquites—an Atlantic assemblage. Petrographical provinces are therefore clearly not permanent.

Study of the geological relations of igneous rocks clearly reveals that there is a general correspondence in both time and space between igneous action and movements of the earth's crust, whether these be simply vertical movements of elevation and depression or tangential movements of folding and overthrusting which build up great mountain chains. As in crustal movements so in igneous action, periods of activity have alternated with periods of quiescence. The movements of compression which led to the folded mountain chains fringing the Pacific were accompanied and followed by widespread volcanism, and the movements of depression which in Tertiary times led to the formation of the Great Rift valley of east Africa were attended and followed by a great suite of volcanic eruptions. The interdependence of igneous action and crust movement is even of a still more intimate kind, for not only the distribution of igneous rocks, but the distribution of different kinds of igneous rock is seen to stand in unmistakable relation to the great tectonic structures of the earth. The examples referred to above are illustrative of this conclusion. The volcanoes of the Pacific cordillera erupted calcic andesites and basalts, and are associated with granodiorite and quartz-diorite intrusions; the eruptions associated with the African Rift valley are in contrast, being of alkali type and including soda trachytes, phonolites, and related alkali lavas. Whether attention is confined to Tertiary igneous rocks or extended to those of earlier date, the conclusion is enforced that rocks of the Pacific suite are closely associated with folded mountain chains and appear in regions subject to movements of compression and lateral thrust, and that the Atlantic or alkali suites are associated with regions of subsidence, subject to tension and faulting. The volcanic rocks of oceanic islands are dominantly olivine basalts and with these, though in minor development, are associated typical Atlantic differentiates—trachyte and phonolite. More siliceous lavas have not been frequently reported, but their occurrence with basalts and trachytes in an oceanic environment attests an intimate genetic relationship and adds support to the theory that granitic differentiate can derive from parental basaltic magma. Quartz trachyte or alkali rhyolite have been thus recorded in the inner Pacific at Easter Island and in Tutuila (Samoa), in the south Atlantic (Bouvet Island) and in the Indian ocean (Kerguelen archipelago).

The tectonic environment of rocks of the Mediterranean suite is less clearly defined. In general their spatial arrangement in relation to the Pacific and Atlantic suites reflects their intermediate position. They are characteristic of the region lying between the orogenic zones and the forelands or regions of subsidence. The position of the potassic Roman province in relation to the Alpine orogenic zone and the alkali (Atlantic) basin of the west Mediterranean illustrates this association clearly.

Between many calcic, sodic and potassic suites no sharp line of division is to be recognized, and in their relative distribution

upon the face of the globe may be seen the influence of tectonic processes as an external factor exerting a profound influence on the trend of differentiation. *See* also references under "Petrology" in the Index.

BIBLIOGRAPHY.—Most textbooks of geology treat petrology in more or less detail (*see* GEOLOGY: *Bibliography*).

Elementary books on petrology include: A. Harker, *Petrology for Students,* 8th ed. rev. by C. E. Tilley, S. R. Nockolds and M. Black (1954, reprinted 1956); F. H. Hatch, A. K. and M. K. Wells, *The Petrology of the Igneous Rocks,* 10th ed. rev. (1950); S. J. Shand, *Eruptive Rocks,* 4th ed. rev. (1950); H. Williams, F. J. Turner and C. M. Gilbert, *Petrography* (1954); E. E. Wahlstrom, *Petrographic Mineralogy* (1955); E. W. Heinrich, *Microscopic Petrography* (1956); A. Sawarizki, *Einführing in die Petrochemie der Eruptivgesteine,* 2nd ed. rev., Russian trans. (1954); W. W. Moorhouse, *The Study of Rocks in Thin Section* (1959).

PETRONIUS ARBITER (GAIUS or ? TITUS PETRONIUS) (d. A.D. 66), Roman voluptuary, poet and the reputed author of the *Satyricon,* the first western European novel. Tacitus gives a graphic account (*Annals,* xvi, 18–19) of his character and the manner of his death. He was an able man, who distinguished himself as governor of Bithynia and consul; but his chief talent lay in the pursuit of pleasure, in which he displayed such exquisite refinement as to earn the unofficial title of the emperor Nero's "arbiter of elegance" (*arbiter elegantiae*). Being suspected of conspiring against the emperor, he was ordered to commit suicide; his last hours were passed in amusements, social pleasures and the composition of a scurrilous catalogue of Nero's debaucheries.

The identification of this Petronius with the author of the *Satyricon* is, notwithstanding all that has been urged to the contrary, reasonably certain. The atmosphere of the work and the internal evidence point to the Neronian period, and it seems unlikely that two different men of the same name and so similar in character and outlook can have existed at the same time.

The *Satyricon* (properly perhaps *Satyrikon liber,* "Book of Satyrlike Adventures") is a "picaresque" romance. It relates the wanderings and escapades of a disreputable trio of adventurers, the narrator Encolpius ("Embracer"), his friend Ascyltos ("Scot-free") and the boy Giton ("Neighbour"—a euphemism). The surviving portions probably represent about one-tenth of the complete work. Some semblance of unity is imparted to the episodic narrative by a wrath motif recalling the *Odyssey* and the *Aeneid:* the narrator is pursued by the enmity of Priapus, whose divinity he apparently offended in a lost portion of the work. The *Satyricon* has obvious affinities with the later Greek prose romances, particularly in the rhetorical flavour which pervades it, but its immorality, or rather amorality, sets it in a class apart from them. Its tone recalls the notorious predilection of Nero and his court for low life and suggests that it may have been composed specially for their amusement. Its literary ancestry is complex and can only be guessed at. The loose narrative framework encloses a number of detached tales of the so-called "Milesian" type, the ancestor of the smoking-room story, a classic instance being the famous "Widow of Ephesus" (*Satyricon,* ch. 111–112); in this the *Satyricon* resembles the later *Metamorphoses* of Apuleius. Other features, however, recall the "Menippean" satire (represented in Latin by M. Terentius Varro): namely, the mixture of prose and verse in which it is composed; and the digressions in which the author airs his own views on various topics having no connection with the plot.

The most remarkable of these digressions, which are the only parts of the work which may properly be called satire, is the passage relating to contemporary epic poetry (ch. 118); it is followed by a hexameter poem of 295 lines on the civil war between Caesar and Pompey, apparently intended as a criticism (not a parody) of Lucan. Whether Petronius had a Greek model or whether the fusion of genres represented by the *Satyricon* was his own invention must, in the present state of the evidence, remain uncertain.

The longest and the best episode is the so-called *Cena Trimalchionis* or "Banquet of Trimalchio" (ch. 26–78), a description of a dinner party given by Trimalchio, an immensely rich and vulgar freedman (former slave) of oriental origin, to a group of friends and hangers-on. Its length appears disproportionate even to the presumed original size of the *Satyricon* (though the story of Cupid and Psyche in Apuleius offers a partial analogy), and it has little or no apparent connection with the plot. The scene is a Greco-Roman town in Campania, possibly Puteoli (Pozzuoli), and the guests, mostly freedmen like their host, are drawn from what corresponded to the *petit bourgeois* class. Trimalchio is the quintessence of the parvenu, a figure familiar enough in ancient satirical literature, but especially so in the 1st century A.D., when freedmen as a class were at their most influential. The setting exemplifies a literary form stemming from Plato's *Symposium* and already employed for satirical purposes by Horace (*Satires,* ii, 8).

Two features distinguish Petronius' *Cena* from other ancient examples: its extraordinary particularity and realism and the figure of Trimalchio. It is obvious that the table talk of the guests in the *Cena* is based on personal observation of provincial societies. The speakers are beautifully and exactly characterized and their dialogue, quite apart from the invaluable evidence for colloquial Latin afforded by the vulgarisms and solecisms in which it abounds, is a humorous masterpiece. Trimalchio himself, with his vast wealth, his tasteless ostentation, his affectation of culture, his superstition and his maudlin lapses into his natural vulgarity, is more than a typical satirist's figure. That some of his idiosyncrasies are taken from life is proved by Seneca's description of Calvisius Sabinus (*Epistles,* xxvii, 5); and, if due allowance is

made for comic exaggeration, little about him is actually incredible. As depicted by Petronius, however, he is one of the great originals of literature, fit company for Shakespeare's Falstaff or R. S. Surtees' Jorrocks. Development of character for its own sake was hardly known in ancient literature: the emphasis was always on the typical, and the classical rules as expounded by, for instance, Aristotle and Cicero, laid down that character was secondary to more important considerations such as plot. Petronius, in his treatment of Trimalchio, transcended this almost universal limitation in a way that irresistibly recalls Dickens, and much else in the *Cena* is Dickensian—its exuberance, its boisterous humour (rare in ancient literature, where wit predominates) and its loving profusion of detail.

The rest of the *Satyricon* is hardly to be compared with the *Cena*. It offends not so much by its indecency as by the selfish and flippant hedonism which colours it throughout (a debased Epicureanism: *see* the poem at the end of ch. 132). This, allied to a Latin of unmatched grace and elegance, earned for Petronius (from Justus Lipsius) the title *auctor purissimae impuritatis*, "writer of the purest impurity." The few poems transmitted separately from the *Satyricon* under Petronius' name do nothing to enhance his reputation. To the middle ages he was known as the author of moral maxims, preserved in fragmentary excerpts; his popularity in modern times dates from the publication in 1664 of the previously unknown *Cena Trimalchionis*, discovered in a manuscript at Trau (Trogir) in Dalmatia.

BIBLIOGRAPHY.—The standard edition of the text is by F. Bücheler, 6th ed. rev. by G. Heraeus (1922); there are also editions by M. Heseltine with Eng. trans. (1913), by A. Ernout, 3rd ed., with Fr. trans. (1950) and, of the *Cena Trimalchionis* only, by W. B. Sedgwick, with introduction and commentary (1950). Translations abound; the best-known English version is by W. Burnaby (1694). For a general introduction *see* A. Collignon, *Étude sur Pétrone* (1892); E. Thomas, *Pétrone* (1912); G. Bagnani, *Arbiter of Elegance* (1954). *See* further Sir S. Gaselee, "The Bibliography of Petronius," *Trans. Bibl. Soc.*, vol. x (1910); W. Kroll, "Petronius," in Pauly-Wissowa, *Real-Encyclopädie der classischen Altertumswissenschaft*, vol. xix (1937); R. PETRONIUS MAXIMUS: *see* MAXIMUS.

PETROPAVLOVSK, capital of the North Kazakhstan *oblast* in the Kazakh Soviet Socialist Republic, U.S.S.R., is situated at the point where the Ishim River is crossed by the Trans-Siberian Railway. Pop. (1959) 131,453. In addition to the processing of food and clothing, its industries include timber and brick making. There are various technical training establishments, a museum, a musical institute, and a theatre. (G. E. WR.)

PETROPAVLOVSK-KAMCHATSKI, a town and administrative centre of Kamchatka *oblast* in the Russian Soviet Federated Socialist Republic, U.S.S.R., stands on the eastern Pacific coast of the Kamchatka (*q.v.*) peninsula and has a good natural harbour on the northeastern shore of the landlocked Avachinskaya Gulf. Pop. (1959) 85,582. The town was founded in 1740 during V. J. Bering's Kamchatka expedition. In 1854, during the Crimean War, an Anglo-French attack on Petropavlovsk was repulsed. The modern town is a whaling centre and has a shipyard, timber mills, and engineering works. Freighters and fishing boats are built, and fishing nets are made. It is the terminus of the only road in the peninsula, through the valley of the Kamchatka River. It has a pedagogic institute. (R. A. F.)

PETRÓPOLIS, a city of the state of Rio de Janeiro, Brazil, in an elevated valley of the Serra de Estrêla or dos Orgãos mountains, 2,634 ft. (803 m.) above sea level, is 27 mi. (43 km.) N of Rio de Janeiro, with which it is connected by railway and highway. It was founded in 1845 by Julius Frederick Knoeller, and was sponsored by Dom Pedro II, the Brazilian emperor for whom it was named. The emperor was attracted to the city's relatively cool climate—5° C. (9° F.) lower than Rio de Janeiro during the summer—and held court there during the warmer months, attended by public officials and members of the diplomatic corps.

The ornate royal palace, surrounded by luxuriant gardens, houses the Museu do Imperio (Museum of the Empire) that contains many of the possessions of John VI of Portugal, who resided in Brazil for several years, and of the two Brazilian emperors, Dom Pedro I and Dom Pedro II. The cathedral of the town is of 13th-century French Gothic design. There is a variety of manufacturing industries in the city and a short distance away are rich farm lands. Pop. (1960) 93,849. Quitandinha palace, a leading resort centre, is about 3 mi. (5 km.) S of Petrópolis on the highway to Rio de Janeiro. (J. J. J.)

PETROZAVODSK, a town and the capital of the Karelian Autonomous Soviet Socialist Republic, U.S.S.R., stands on the western shore of Lake Onega, south of the outfall of the Shuya River and 185 mi. (318 km.) NE of Leningrad. Pop. (1959) 136,294. The town (its name means "Peter's factory") was founded in 1703 by Peter the Great as an ironworks to supply ordnance to his new capital of St. Petersburg (now Leningrad) and the Baltic fleet. The metallurgical industry still persists and has been joined by timber working (furniture, prefabricated houses, and skis), ship repairing, fish canning, brewing, and distilling. Petrozavodsk is on the main Leningrad-Murmansk Railway, with a branch line to Suoyarvi and Finland. There are a university, a pedagogic institute, the Karelian branch of the Academy of Sciences, and many other scientific and educational establishments. (R. A. F.)

PETRUCCI, OTTAVIANO DE' (1466–1539), Italian printer of music, whose collection of chansons, *Harmonice Musices Odhecaton A* (1501), was the first book of part music to be printed from movable type. Born at Fossombrone, near Ancona, he moved to Venice about 1490. He held music printing monopolies first at Venice, where he worked from 1498 to 1511, and later at Fossombrone. In 1536, at the request of the Venetian Senate, he returned to Venice, where he died in 1539. His 61 music publications contain Masses, motets, chansons, and *frottole* by many of the foremost composers of the 15th and early 16th centuries, Josquin Després, Jean d'Okeghem and Loyset Compère among them. He also published the first book of printed lute music, Francesco Spinaccino's *Intabolatura de Lauto* (1507). (D. Po.)

PETRUS AUREOLI (PIERRE AURIOL, ORIOL OR D'ORIOL) (*c.* 1280–1322), French Franciscan, theologian, and philosopher known honorifically as *Doctor facundus*, "the eloquent teacher," was born near Gourdon in Quercy. Having studied in Paris and taught in Bologna and Paris, he became provincial of his order for Aquitaine (*c.* 1320) and archbishop of Aix-en-Provence (1321). Criticizing both Thomas Aquinas and Duns Scotus, he promoted an individualistic empiricism, supported by a nominalistic-conceptualistic doctrine of universals which in some ways anticipated William Ockham (*q.v.*). His *Commentary on the Sentences* was first printed in Rome, two volumes (1596–1605).

See A. Teetaert, "Pierre Auriol," in A. Vacant (ed.), *Dictionnaire de théologie catholique*, xii (1934). (L. M.-Po.)

PETTY, SIR WILLIAM (1623–1687). English political economist and statistician, one of the founders of economic thought and demographic and economic statistics, was born at Romsey, Hampshire, May 26, 1623. Having studied medicine at the universities of Leiden, Paris and Oxford, he was in turn seaman, medical student, physician, professor of anatomy at Oxford, professor of music in London, inventor, surveyor and landowner in Ireland and a member of Parliament. He died in London on Dec. 16, 1687.

A protagonist of the empirical scientific doctrines of the newly founded Royal Society, of which he was a founder-member, Petty was one of the leading pioneers of political arithmetic; *i.e.*, "the art of reasoning by figures upon things relating to government." His *Essays on Political Arithmetick* and *Political Survey or Anatomy of Ireland* (1672) presented population estimates and rough calculations of social income. His methods seem crude and audacious by modern standards, but Petty was not unaware of their limitations. His ideas on monetary theory and policy, including the quantity theory, were developed in *Verbum Sapienti* (1665) and *Quantulumcunque concerning Money, 1682* (1695). But his main contribution to political economy was *Treatise of Taxes and Contributions* (1662), in which he expounded what should be the main economic functions of the state. In doing so he touched on the fundamental problem of the theory of value, treating the labour

necessary for production as the main determinant of exchange value and seeking a standard of value in the necessary sustenance of a man for a day. Petty—an advocate of religious toleration—favoured allowing scope to the natural forces of individual self-interest and "rather complying with the motions of nature than contradicting it with vehement administratives." But unlike liberals after Adam Smith he considered the maintenance of a high level of employment by monetary and fiscal policies and by public works to be a duty of the state.

See *Economic Writings of Sir William Petty,* ed. by C. H. Hull, 2 vol. (1899). (T. W. H.)

PETUNIA, the common and generic name of popular garden plants of the nightshade family (Solanaceae), native to South America, mostly from Brazil and Argentina. They are sticky herbs, with soft, flabby leaves and weak, straggling stems. Petunias may be divided into two main divisions: bushy types, both high (7–15 in.) and dwarf (4–6 in.), used as bedding plants; and sprawling or weak-stemmed types, often called balcony petunias, useful for window boxes. Modern petunia varieties have typically funnel-shaped flowers, only slightly asymmetrical, and variously crisped, fringed, or ruffled; double varieties have also been developed. Amply watered and in a sunny location, these showy plants will bloom profusely all summer, yielding blossoms of pure white and cream through various shades of red and blue to deep violet; variegations are not uncommon. Some of the large-flowered types are easily beaten down by rain and should be staked.

ROCHE

BALLERINA, HORTICULTURAL VARIETY OF GARDEN PETUNIA (PETUNIA HYBRIDA)

All the petunias are annuals and are not frost-hardy. They may be started from seed sown indoors and just barely covered with fine-grained soil eight to ten weeks before outdoor planting is safe. When warm weather has arrived, both seeds and seedlings can be planted outdoors in almost any ordinary garden soil. They do well in almost any temperate locale. (N. Tr.; X.)

PETWORTH, a town of West Sussex, Eng., lies 14 mi. (23 km.) NE of Chichester by road. Pop. (1961) 2,347. Petworth (Peteorde in Domesday Book, Puetewurth in 1181) under Edward the Confessor was an alodial manor held by Edith (probably his queen), and in 1086 Robert Fitz-Tetbald held it of Roger de Montgomery, earl of Shrewsbury. Later it became one of the principal seats of the family of Percy. Standing in a large park is Petworth House (National Trust) with a 13th-century chapel; the manor house was almost wholly rebuilt between 1688 and 1696 by the duke of Somerset. The south front was rebuilt in 1869–72. It is remarkable for its magnificent collection of pictures and its wood carvings by Grinling Gibbons and Jonathan Ritson (1776?–1846). (L. F. S.)

PEUTINGER TABLE, a copy of a Roman map, made in A.D. 1265 by a monk of Colmar on 12 sheets of parchment. Eleven sheets are now in the Hofbibliotek in Vienna. The dimensions are 268 x 13½ in. (6.82 x 0.34 m.). The copy was found by Conradus Celtis in 1494 and bequeathed by him to his friend Konrad Peutinger (1465–1547) of Augsburg.

The shape of the map, an elongated rectangle, obviously causes a grave deformation of the Roman world, the distances from north to south being compressed and those from east to west being unduly extended. The sea is even more restricted than the land, so that the Mediterranean becomes a narrow canal. Errors, major and minor, are therefore multitudinous. For example Thessalonica lies directly east of Piraeus and the Nile runs mainly west to east. The map is in six colours (black, red, green, yellow, blue, and rose); features and facilities in towns are indicated by small sketches.

Opinions have differed as to how closely the lost original depended on Roman itineraries and world maps, such as the map of Agrippa (the table goes beyond the frontiers of the Roman Empire to the east). The dependence cannot be denied and may have been fairly close. *See* also Map: *History: Greece and Rome.*

Bibliography.—E. Desjardins, *La Table de Peutinger* (1869–74); J. W. Kubitschek in Pauly-Wissowa, *Real-Encyclopädie der classischen Altertumswissenschaft,* x, 2126–44 (1919); F. Gisinger, *ibid.,* xix, 1405–12 (1938). (J. J. T.)

PEVENSEY, a village in the Hailsham rural district, East Sussex, Eng., 5 mi. (8 km.) E of Eastbourne, consists of two parts: the old village, once an important seaport and a limb of the Cinque Port of Hastings, now a mile from the sea; and Pevensey Bay, a small holiday resort on the coast. Pop. (1961) 2,151. The Roman Anderida (*c.* 250) was a fort of the Saxon shore and the remains of its walls and towers are one of the finest examples of Roman building in England. William I landed at Pevensey in 1066 and soon afterward Robert, count of Mortain, built a castle within the Roman walls. The gatehouse, towers, and walls of the inner courtyard were added in the mid-13th century. Pevensey was from Saxon times the head of the Rape of Pevensey, and the Early English church of St. Nicholas, the tiny courthouse, and the Mint House show its past importance. It was a borough from Saxon times until 1883. From the 13th century onward the silting up and reclamation of the Pevensey Levels brought about the port's decline. *See* also Sussex. (G. C. B.)

PEWEE, more properly called wood pewee (*Contopus virens*), is a common bird of the American tyrant flycatcher family (Tyrannidae). Smaller than a sparrow, it is olive brown above and whitish below, with two whitish wing bars. The pewee is a gentle, unsuspicious species that perches on a dead branch in open woodland and turns its head constantly as it looks for flying insects. These it captures with a graceful looping flight, punctuated by an audible snap of its broad, flat bill. The little flycatcher then returns to the original branch or a new observation post. Periodically its call is heard, a plaintive "pee-a-wee," and sometimes a descending "pee-er." In the same shady woods, usually saddled on a bare horizontal limb and camouflaged with lichens, is the shallow nest, woven of fine grass, moss, and strips of inner bark. There are two or three creamy white eggs, wreathed about the large end with brown and lavender, which hatch after an incubation of 13 days. The young are fed and cared for in the nest for 15 or 16 more days by both parents before fledging. The eastern wood pewee (*Contopus virens*) breeds in eastern North America and is replaced in western North America by the very similar western

EASTERN WOOD PEWEE (CONTOPUS VIRENS), A COMMON BIRD OF THE AMERICAN FLYCATCHER FAMILY. "PEE-WEE" IS A CLOSE APPROXIMATION OF THE BIRD'S CALL

wood pewee (*C. sordidulus*). Both winter as far south as northwestern South America. (W. J. Be.)

PEWTER, an alloy, the basis of which is tin. Modern pewter is a tarnish-resistant alloy composed of approximately 91% tin, 7.5% antimony, and 1.5% copper; the best grades contain no lead. The copper adds ductility and desirable working properties while antimony serves to whiten the alloy and to impart a hardness unknown to old pewter. Old pewter, first used nearly 2,000 years ago by the ancient Orientals and Romans, contained sufficient lead to cause the surface to darken with age. There are two schools of thought among pewter collectors: some prefer the dark satin-like sheen of old pewter while others prefer modern pewter which retains its brightness indefinitely and lends itself to a whole gamut of finishes from a crisp bright finish to a soft satin sheen.

Pewter played an important part in the development of civilization as a medium for artistic expression and as a material from which domestic utensils were fashioned. Pewter exceeds most other metals in ductility and ease of working. It may be stretched, compressed, and bent into almost any desired shape; and it does not harden or stiffen sufficiently on coldworking with tools for annealing to be necessary. Modern methods of manufacture differ considerably from those of the early craftsmen, which involved casting, turning, and hammering. Much of the flat and hollow ware is spun on a lathe instead of being cast; the stamping press is used frequently to produce such shapes as oval trays and gravy boats. Casting methods are still essential for making handles, feet, knobs, and hinges and for heavy ornamental pieces. Pewter articles can be hammered into shape, the surface can be raised or stretched, surface lines can be emphasized by chasing and embossing, and decorative effects can be achieved by etching. Machine methods for polishing have added interesting possibilities in new and artistic finishes.

Modern Pewter.—Modern pewter is somewhat softer than brass or bronze. In spite of its softness, it must be classed as one of the most durable metals and as one which will resist oxidation almost indefinitely. Utensils made from pewter have a high resistance to almost all weak acids: food and drink may be served in them without fear of chemical action.

Modern pewterware falls into two types: antique and modern. For the person who prefers antique pewterware, there are reproductions of early masterpieces of the American colonial period. For instance, a complete line of Williamsburg reproductions are available, some of which are actually cast from original molds. For those who desire modern pewterware, there is a wide variety of articles such as coffee and tea services, plates, trays, water jugs, tankards, candelabra, serviette rings, bowls, flasks, cigarette and jewelry boxes, spoons, trophies, ship models, pepper and salt shakers, ashtrays, and communion cups. Most modern manufacturers, in adapting original designs or producing new designs, have kept the bold simple lines which are the chief charm of pewter.

The revival of interest in pewter can be attributed to several factors. For example, the public has become educated to the charm and beauty of nontarnishing pewter; contemporary craftsmen are using pewter in new ways and in striking designs. Working with pewter has been introduced as an important activity in industrial arts courses in the schools and the home workshop.

Collections.—The historical background of old pewter is extensive and many historical collections can be seen in museums throughout the world. Famous collections are on display in the Victoria and Albert Museum in London, the Smithsonian Institution in Washington, D.C., and the University of Copenhagen in Denmark. There are more than a dozen large pewter collections in the United States. (*See* list of museums, B. N. Osburn and G. O. Wilber, *Pewter*, 1947.)

History.—Specimens of Roman pewter excavated in England leave no doubt that pewterware was made in England by the Roman legions. From the Renaissance, the use of pewter in England had been firmly established in the church and for domestic purposes. Pewter chalices had replaced wooden vessels before the end of the 11th century; until the 15th century it was customary to bury a pewter chalice with the priest. After the Reformation and throughout the 17th and 18th centuries, a large number of pewter vessels were found, especially flagons, alms dishes and collection plates. It was customary for every pewterer to strike his "touch" or mark: these marks were made with a steel die into which some ornamental design with the initials of the maker had been cut. The mark indicated membership in a guild called the Worshipful Company of Pewterers, chartered by the crown in 1503. Records of touchmarks were destroyed in the great fire of 1666. The activities of the company prospered and pewterware became an important household item. Plates, saucers, tankards, mugs, candlesticks, and mustard pots are excellent examples of some commonly used articles in English homes until the period when china and porcelain appeared. During World Wars I and II many valuable pieces of pewter relegated to the attic were sold for scrap and lost forever. It is surprising that so much pewter has survived and that it is possible to form a representative collection of pewter items from at least the late 17th century to the middle of the Victorian era.

Much fine pewterware was made in other parts of continental Europe. The earliest known date on a pewter article made in Holland is 1331. In the 17th century, pewter played an important part in middle-class homes and in the inns. The modern pewter industry continues the old tradition. Century-old, well-tried models are still being made but craftsmen have given new shapes to the classic material by harmoniously combining usefulness and beauty. Dutch pewterware is plentifully available and is exported to all countries into which importation is allowed.

The manufacture of pewterware began in Sweden before the end of the 13th century. Guild rules existed as early as 1485 when pewterers were required to stamp their wares. A rose-and-crown mark, much in evidence in the 17th century, denoted the highest quality. The artistically brilliant period of pewter in Sweden was the 18th century when it served widely for table wares and candlesticks. The decline occurred as in other countries but manufacture was revived in 1924.

Germany had established a pewter industry at Augsburg and Nürnberg in the 14th century. During the next four centuries, pewter was the most versatile metal available and wares of every kind were made. The treatment of pewter in relief was quite common as, for example, the plates with portraits of emperors or medallions of Biblical scenes. German hostels afforded much in the way of tankards and drinking vessels. After World War II, the pewter industry in Germany had revived strongly in the towns of Regensburg, Württemberg, Diessen and Nabburg.

The rise of pewter in France and Belgium was contemporary with that in other European countries. In France the most interesting period was the 16th century. Highly ornamented pieces have been found which were associated with the name of François Briot, the greatest of French pewterers. His well-known Temperantia salver and ewer are covered with ornament in relief. On the ewer are figures of the cardinal virtues, while on the dish are figures of Minerva and the seven arts, with the four elements and Temperance in the centre. Fine examples of his work are preserved in the Cluny Museum, Paris. Little of the ancient pewter remains in Belgium because so much disappeared during the repeated wars and invasions.

Pewter was used much in the households of colonial America. The earliest pewterers came from England, bringing their traditional styles with them. The period which marked its greatest production was the 150 years between 1700 and 1850. Boston, New York and Philadelphia were the main centres of manufacture. Every kind of utensil was made which was in any way requisite for domestic purposes: plates, bowls, spoons, tankards, candlesticks, and lamps were made in enormous quantities. With the advent of cheap pottery, particularly plates, the pewterers turned their efforts to the manufacture of coffee pots and these became the mainstays. In the 20th century, there came a revival of interest in colonial period pewter; several firms took up the manufacture of antique reproductions and then branched into new designs which found favour. It is apparent that in spite of other available materials, pewter retained its hold and popularity upon American taste long after it had ceased to interest the European public. During World War II and for a number of years thereafter, the manufac-

ture of pewter was not allowed because tin was reserved for essential purposes. Restrictions were removed in 1953 and manufacturers made up lost ground by leaps and bounds. Since then, the world production of modern pewterware has exceeded the amount of pewter produced in any similar period in the history of the industry. *See* also ANTIMONY; TIN.

PEYOTISM is the use by American Indians of peyote (*e.g.*, mescal: *Lophophora williamsii*), spineless cacti native to northern Mexico and southwestern U.S. The word peyote seems to be a Spanish version of the Nahuatl term *peyotl*. When eaten, peyote produces extraordinary psychophysiological effects that vary with the social situation. Effects reported from laboratory studies differ from those observed under ritual conditions. The medically active principle in peyote is mescaline (3,4,5-trimethoxyphenethylamine), an alkaloid drug classified by pharmacologists as a hallucinating agent (*see* NEUROPHARMACOLOGY AND PSYCHOPHARMACOLOGY).

Of the two major forms of peyotism, the old peyote complex is the earlier form; it flourished prior to the 20th century. Peyote was used primarily as medicine and to induce visions by individuals seeking supernatural revelation. It was also used in groups as an auxiliary in tribal dancing rites, evidently to induce a trance state. Little is known about the origin and distribution of the old peyote complex; however, peyote is depicted in pre-Columbian remains in Mexico. Documents from the 16th to the 18th century report the old peyote complex as extending from southern Mexico to northern New Mexico and Oklahoma. In the 1960s the old peyote complex existed in Mexico with diminished importance.

The peyote religion is a more recent form of peyotism that developed during the second half of the 19th century. The religion is practised by a voluntary organization, with a rite of prayer, singing, and quiet contemplation, centred on peyote as a symbol of spirits being worshiped and as a sacrament. Peyotism as a fully developed religion probably originated about 1885 among Kiowa and Comanche in Oklahoma from an earlier Apache peyote rite. After 1891 it spread rapidly and became the most widespread indigenous Indian religion, extending from the Great Lakes to the Cascade and Sierra Nevada mountains in the U.S. and to the Rocky Mountains of Canada. Groups practising the peyote religion were incorporated in 1918 as the Native American Church in Oklahoma. In the 1960s this church claimed 200,000 members.

Peyotism has the basic traits usually found in religions: a doctrine, ethics, and ritual. Most peyotists consider themselves Christians, holding peyotism to be the Indian version of Christianity; they accept the Trinity and ethics of white Christians.

Doctrine of the Peyote Religion.—Peyotist doctrine or religious theory consists of a belief in the existence of power, spirits, and incarnations of power, and is stated by peyotists as follows:

Power.—Power is the Indian equivalent of mana (*q.v.*). It is an immaterial and invisible supernatural force that produces characteristic physical effects and can be transferred from one thing to another under the proper ritual conditions. Man needs power to be successful and healthy; without it he becomes unsuccessful and ill. Spirits are immaterial personifications of power. The peyotist pantheon consists of what may be called white and Indian spirits.

White Spirits: the Trinity.—God is equated with the Great Spirit and acknowledged as the supreme being and the ultimate source of all power; he controls the destiny of everything in the universe, including man. Whether he is held to be the creator spirit as well depends upon the tribe. In some tribes Jesus Christ is the culture hero (often equated with the traditional culture hero) who gave the white version of Christianity to the whites and peyotism to the Indians. In other tribes Jesus is a guardian spirit, rejected by the whites who murdered him, who now looks after the equally rejected Indians. Another of Jesus' roles is that of intercessor spirit between God and man; the Holy Ghost has been adopted as part of the Trinity.

Indian Spirits.—The spirit called Waterbird is usually identified as the snakebird (*q.v.*). Some equate Waterbird with the traditional Indian thunderbird, others with the white Christian dove. Most often it has the role of a messenger spirit that carries man's prayers to God. In many tribes peyote itself is personified as Peyote Spirit, generally with the guardian spirit aspect of Jesus in white Christianity. Peyote Spirit is a compassionate male being, always benevolent, sympathetic, and helpful.

Incarnations.—Incarnations are material embodiments of power, and peyote is the prime incarnation. It was given to the Indians by God because he took pity on them for being a poor, weak, helpless, and ignorant subject people. When one eats peyote he absorbs and can use its power. Peyote eating thus is a sacrament.

The next most important incarnation of power is the ritual water drunk at midnight and in the morning. Water is needed by all living things, and therefore all water is sacred; the water is prayed over and blessed so that it acquires additional power. The morning water is particularly sacred because it is brought in and prayed over by the wife or other close female relative of the leader. She represents womanhood as the source of human life ("the mother of us all"). In some tribes she also symbolizes Peyote Woman to whom the rite was revealed.

The foods used in the morning communion breakfast (usually corn, meat, and fruit) also contain power, for they represent the nutrients needed for human life.

Ethics and Eschatology.—Peyotists are expected to follow a way of life called the Peyote Road, an ethical code with four main parts:

Brotherly Love.—Members should be honest, truthful, friendly, and helpful to one another. This is conceived as a spelling out of the Golden Rule (*q.v.*).

Care of Family.—Married persons should not engage in extramarital affairs and should cherish and care for each other and their children. Money should be spent on the family as a whole, rather than selfishly.

Self-Reliance.—Members should work steadily and reliably at their jobs and earn their own living.

Avoidance of Alcohol.—There is a maxim: "Peyote and alcohol don't mix."

Ritual.—Characteristically, but not always, the rite (called a meeting) is held in a Plains-type tepee. The all-night ceremony usually lasts from about 8 P.M. on Saturday to 8 A.M. on Sunday and essentially involves prayer, solo and unison singing, eating the sacramental peyote, and contemplation.

The worshiper eats peyote under the proper ritual conditions in order to obtain power to commune effectively with God and the other spirits. Concentration on such communion is designed to lift the worshiper to an exalted level of spiritual sublimity. In the Great Plains culture area the individual traditionally went off in isolation, subjected himself to ordeals so that he would be pitied, and prayed until some spirit appeared in a vision to give him personal power. Peyotism changes the pattern somewhat since there is a collective rite; but most of the time is spent in contemplation —in a kind of collective isolation. Most persons do not find peyote pleasant to take, and find it difficult to sit on the ground all night in one position. These are peyotist equivalents of the traditional ordeal. In the prayer for assistance God and the other spirits are asked for pity and help through peyote. The worshiper is expected to put away all evil thoughts, to be conscious of his inadequacy, humble, sincere in wanting the benefits of peyote, and to concentrate on the effort.

The successful worshiper experiences a revelation that in most cases takes the form of a vision in which he sees or hears a spirit. In some cases the revelation takes the form of a mystical state, described as the unification of all immediate experience with God.

In either circumstance the individual has a vividly direct experience, rather than revelation obtained from inference or hearsay. It may be interesting to know what others have to say; but all that really matters to the true peyotist is what he has directly experienced—what has been revealed to him personally by peyote. "The only way to find out about peyote is to take it and learn from peyote yourself."

Usually the visions are of God, Jesus, or some other spirit presenting a revelation that is related to the personality and problems of the individual. One peyotist may be comforted by learning more of peyote doctrine or may see or hear departed loved ones. Another may be shown how to solve some problem in daily life; or he may be reproved for evil thoughts and deeds and warned to repent.

Peyotists express these results of contemplation as "learning from peyote," and consider peyote an inexhaustible teacher. A stock statement is: "You can use peyote all your life, but you'll never learn all there is to know about peyote. Peyote is always teaching you something new." Peyote is also believed to be a universal panacea for bodily as well as spiritual ills. Peyotist etiology is based upon traditional Indian beliefs: disease is produced either by insufficient power or by a foreign object. Thus the sick person is told to eat enough peyote to absorb the amount of power needed to restore health; in more serious cases to pray to God and other spirits for power over and above that which is obtained from eating the peyote. The invalid may do this for himself, but in the most serious illnesses a doctoring meeting is held so that others can help pray. The sick person may vomit as a result of eating peyote; in this way it is held that the foreign object which caused the disease is ejected from the body; the patient then eats more peyote to obtain the power necessary for health. (Vomiting is believed also to purge one of spiritual uncleanness.)

Legal Status.—Peyote religion has long been controversial. In 1620 the inquisitor of New Spain prohibited the use of peyote by all Christians. Starting in Oklahoma in 1899, and continuing to the California antipeyote law of 1958, the use or sale of peyote was prohibited by 15 states. By the 1960s some of these states (Oklahoma, Iowa, Montana, New Mexico, Texas, and Utah) had revised their laws to allow peyote in religious services. In the Arizona Superior Court (Flagstaff), a law prohibiting the use of peyote was declared (1960) "unconstitutional as applied to the acts of this defendant in the conduct of her religious beliefs" in the case of peyotist Mary Attakai. In 1961 the Arizona Supreme Court dismissed an appeal of the case. In 1962 three Navaho Indians were prosecuted in the Superior Court of San Bernardino County for using peyote in a religious ceremony contrary to California law. By 1964 the California Supreme Court had set aside their suspended sentences, comparing the practice of carrying peyote in beaded bags with the use of religious medallions and stating: "To forbid the use of peyote is to remove the theological heart of peyotism."

Despite some state laws, the U.S. Congress has rejected nine bills (from 1916 to 1937) that would have prohibited use, sale, and transportation of peyote. However, persons shown to be addicted to peyote can be sent to federal narcotic hospitals under a 1929 law. By the 1960s no such cases had been found; evidence was not available that peyote produces addiction. A Navaho Tribal Council ordinance of 1940 prohibiting peyote on the reservation has been upheld three times in federal courts. In each case (the third was in a Washington, D.C., Court of Appeals, 1962) the court denied itself jurisdiction over Navaho Tribal Council legislation regarding religion.

(J. S. SR.; O. C. ST.)

PFEFFER, WILHELM (FRIEDRICH PHILIPP) (1845–1920), German physiological botanist whose work on osmosis marked an epoch in investigations on the properties of semipermeable membranes and water solutions (*see* SOLUTIONS: *Osmotic Pressure*). He was born in Grebenstein near Kassel on March 9, 1845. After earning a degree in botany and chemistry from Göttingen University in 1865, he spent the next several years studying botany and pharmacy at Marburg University. He continued his botanical studies as a private assistant to Nathanael Pringsheim at Berlin (1869–70) and to Julius von Sachs at Würzburg University (1870–71). In 1871 he returned to lecture at Marburg and in 1873 was appointed lecturer of a higher rank at Bonn University. In 1877 he became a professor at Basel University and later held similar positions at the universities of Tübingen (1878) and Leipzig (1887).

Pfeffer made significant contributions in the following areas of plant physiology: respiration, photosynthesis, protein metabolism, tropic and nastic movements. In 1881 he published the first part of his *Handbuch der Pflanzenphysiologie* (English translation by A. J. Ewart, *Physiology of Plants*, three volumes, 1906), which prevailed for many years as an important text. He died Jan. 31, 1920, in Leipzig. He published more than 100 papers and books.

(W. J. MCI.)

PFITZNER, HANS ERICH (1869–1949), German composer who upheld traditional ideals during the post-Wagnerian era. Born in Moscow on May 5, 1869, he was a pupil at Frankfurt of Iwan Knorr. Between 1892 and 1934 he held posts as teacher and conductor in several German towns, including Strassburg, where he was director of the conservatory and of the opera. His operas include *Der arme Heinrich* (Mainz, 1895), *Die Rose vom Liebesgarten* (Eberfeld, 1901), and *Palestrina* (Munich, 1917), the last being his best-known work. Influenced by the nationalist movements in European music after World War I, Pfitzner was held to reaffirm a specifically German character, though most of his works are written in a traditional Romantic style. Between 1915 and 1919 he attacked modern tendencies in pamphlets on the music drama and contemporary music. His works were widely played in Germany but made little impression in other countries. He died at Salzburg on May 22, 1949.

PFORTE (or SCHULPFORTE), formerly a Cistercian monastery (of which remains can still be seen), later a famous German boarding school. It lies 2 mi. SW of Naumburg, Saxony, German Democratic Republic. The monastery, which had the name Monasterium Sanctae Mariae de Pforta (or *apud Portam*), was established in 1137. In 1540 it was dissolved by Henry of Saxony and in 1543 his successor, Maurice, founded there one of his three Protestant "princely" schools (*Fürstenschulen*), the others being at Grimma and Meissen. The school provided a humanist classical education. Its pupils include Paul Gerhardt, C. F. Gellert, Klopstock, Lessing, Ranke, and Nietzsche. From 1935 to 1945 it was a school for the training of a Nazi elite. After World War II it became a high school for boy and girl boarders receiving a scientific, modern language, or classical education.

See W. Hirschfeld, *Das Zisterzienserkloster Pforte* (1933); F. Heyer, *Aus der Geschichte der Landesschule Pforte* (1944); R. Pahncke, *Geschichte des Zisterzienserklosters Pforte* (1956).

PFORZHEIM, a town of West Germany in the *Land* (state) of Baden-Württemberg, Federal Republic of Germany. It is situated on the northern edge of the Black Forest, where the Nagold and Würm join the Enz River, 31 km. (19 mi.) SE of Karlsruhe by rail. Pop. (1961) 82,532. The inner town, destroyed during the war, has been rebuilt with broad thoroughfares and open spaces along the rivers. Notable buildings include the castle church of St. Michael (13th–15th century), the church of St. Martin (14th century) and the Reuchlin House (containing both history and jewelry museums). Pforzheim has been the main centre of the German jewelry and watch industry since the 18th century; other manufactures include machinery, radio and television apparatus, and paper. The town was a Roman settlement

(Portus), had the status of a city shortly after 1195, and was occasionally the residence of the margraves of Baden-Baden (*q.v.*) and Baden-Durlach. The humanist Johann Reuchlin was born there in 1455, and its Latin School was famous. The town was sacked during the Thirty Years' War and the War of the Grand Alliance. (HE. W.)

PHAEDO (5th–4th century B.C.), Greek philosopher, founder of a short-lived school of philosophy at Elis in the Peloponnese, was born at Elis late in the 5th century B.C. Taken prisoner in the war with Sparta (400–399), he was sold as a slave. In Athens he became acquainted with Socrates, one of whose pupils redeemed him from slavery. Plato named one of his dialogues after him (*see* PLATO: *The Earlier Dialogues*), but Athenaeus says that Phaedo disclaimed all responsibility for the role ascribed to him in it. Aeschines also wrote a dialogue called *Phaedo*. After Socrates' death, Phaedo returned to Elis and set up his own school, of which his pupil Pleistanus became head on Phaedo's death but which Menedemus (*q.v.*) subsequently transferred to Eretria. Phaedo's main interest seems to have been in ethics. Of his own dialogues, all of which are lost, the best known were the *Zopyrus* and the *Simon*. U. von Wilamowitz-Moellendorff tried to reconstruct the content of these from references in later texts.

PHAEDRA, in Greek legend, the wife of Theseus and stepmother of Hippolytus, whom she tried to seduce. *See* HIPPOLYTUS.

PHAEDRUS (fl. 1st century A.D.), Roman fabulist of uncertain date, whose work, though ignored by classical Roman writers, was apparently the first of its kind in Latin and attained great popularity in the middle ages. It seems probable that he was born *c.* 15 B.C. and lived at least until the reign of Claudius. His birthplace was Thrace, whence he went early to Italy and received the customary training in Greek and Latin, studying among other authors, Euripides, Simonides, Ennius and Virgil. A slave by birth, he became a freedman in Augustus' household, but, as the prologue to book iii of his *Fabulae Aesopiae* states, later fell foul of Tiberius' minister Sejanus and was prosecuted and punished. "The fable," wrote Seneca *c.* A.D. 43, "has not been tackled by the Roman genius." If one presses the word "Roman" and recollects Phaedrus' foreign extraction, this statement need not imply ignorance of Phaedrus. The Phaedrus mentioned by Martial (iii, 20, 5) has been identified, but on uncertain grounds, as the fabulist. Fables are placed by Quintilian (i, 9, 2) on the curriculum of the young, but, though "Aesop" is named, Phaedrus is not. Unless Martial's Phaedrus is the same man, the earliest reference to him is in the works of Avianus, who about the end of the 4th century composed 42 fables in undistinguished elegiacs.

Though Ennius, Lucilius and Horace had introduced fables into their poems, Phaedrus was the first writer to latinize whole books of fables. His contribution consists of free versions in iambic metre of Greek prose fables then circulating under the name of "Aesop." His iambic senarius, or six-foot line, conceivably influenced by that of Publilius Syrus, is nearer the rough vigour of Plautus than the monotonous artificiality of Seneca: spondees frequently replace iambs in the second and in the fourth feet. Phaedrus' latinity, apart from a few instances of slipshod syntax and vulgar speech, is close to the Augustan norm. Abstract expressions (*e.g.*, *majestas ducis* = "the emperor") smack of the Latin of the silver age. Original poetic imagery is wanting, and epithets are mainly conventional. Phaedrus plumes himself on his brevity; for this as for his simplicity he merits praise.

The popularity, both in Europe and in the east, of the literary beast fable needs no emphasis. (*See* FABLE.) Even the ubiquitous moral tag subtracts little from enjoyment of such favourites in the Phaedrian corpus as "The Fox and the Sour Grapes," "The Wolf and the Lamb," "The Lion's Share," "The Two Wallets" and "The Pearl in the Dung-heap." Phaedrus considers himself a genuine artist, the pioneer of a genre unattempted by his Roman predecessors, whose poems, combining charm with a serious didactic purpose (*utilitas*), are assured of immortality. His stories are enlivened by various references to contemporary Roman society, and some could be interpreted, especially if the cap fitted, not merely as social but as political satire.

The Recovery of the Text.—Avianus states that Phaedrus wrote five books of fables only; and the first printed edition of Phaedrus, published by Pierre and François Pithou at Troyes in 1596, in fact had its contents divided into five books. At the beginning of the 18th century, however, there was discovered at Parma a manuscript of Nicolaus Perottus (Niccolò Perotto or Perotti; d. 1480), the humanist archbishop of Siponto, containing 64 fables of Phaedrus, of which 30 were new. These new fables were published by G. A. Cassitto in 1808 and next, more correctly, by C. Jannelli in 1809; but these editions were superseded by the discovery of a much better preserved manuscript of Perottus in the Vatican, published by Angelo Mai in 1831. The authenticity of these new Phaedrian fables was for some time disputed, but is now generally accepted, though it is impossible to assign them to their original places in the five books. They are usually printed as an appendix.

Knowledge of Phaedrus' works, meanwhile, can be further extended by a careful investigation of the prose versions of his fables current in the middle ages. Of these the oldest collection existing seems to be that known as the *Anonymus Nilanti*, so-called because first edited by J. F. Nilant (at Leiden in 1709). For his edition Nilant used a manuscript of the 13th century, but the collection itself is associated with a little-known writer called Romulus and may have been made in the Carolingian period or even earlier. Later such collections are the Adhemarian, made by Adhémar de Chabannes; and the Weissenburg, from the monastery of SS. Peter and Paul at Wissembourg in Alsace. After a detailed examination of these three medieval collections, Carl Magnus Zander (*see* bibliography) restored 30 more fables to the iambics of Phaedrus.

BIBLIOGRAPHY.—There are editions of the *Fabulae Aesopiae* by J. P. Postgate (1920), by L. Havet (1895; annotated ed. 1923) and by A. Brenot (with Fr. trans., 1924). *See* further C. M. Zander, *Phaedrus solutus* (1921). (H. H. HY.)

PHAER (PHAYER), **THOMAS** (1510?–1560), English writer, best known for a translation of Virgil's *Aeneid* (1558) which is less medieval in tone than those of Gavin Douglas (1553) and the earl of Surrey (1557). Educated at Oxford and at Lincoln's Inn, London, Phaer was a doctor (M.D. 1559) and lawyer as well as a writer and describes himself as "solicitor to the king and queen in the marches of Wales." He translated, with original additions, a medical text by Jehan Goeurot under the title *The Regiment of Lyfe* (1544). He also contributed to *A Myrroure for Magistrates* (1559) and has been credited with *Natura Brevium Newly Corrected in Englisshe* (1532) and *A Newe Book of Presidentes* (1543). *Seven First Bookes of the Eneidos of Virgill Converted in Englishe Meter* appeared in 1558; it was extended to nine books in 1562. The task, left unfinished at his death (Aug. 1560 at Kilgerran, Pembrokeshire) was completed by Thomas Twyne (1584). (H. H. Ds.)

PHAETHON, in Greek mythology, the son of Helios, the sun-god, and the nymph Clymene. His name means "shining" or "radiant." Taunted with illegitimacy, he appealed to his father, who swore to prove his paternity by giving him whatever he wanted. Phaethon asked to be allowed to drive the chariot of the sun through the heavens for a single day. Helios begged him to ask for something else, as the difficulties and dangers of such a task were insuperable for mortal man. Phaethon insisted, however, and Helios, bound by his oath, let him make the attempt. He set off, but was entirely unable to control the horses of the sun chariot, which came too near to the earth and began to scorch it. To prevent further disaster Zeus hurled a thunderbolt at Phaethon, who fell to the earth at the mouth of the Eridanus, a river later identified with the Po. There his mourning sisters, the Heliades, were transformed into poplars and their tears became amber. The story is fully told in the first and second books of Ovid's *Metamorphoses* and in the 38th book of Nonnus' *Dionysiaca*.

PHAGOCYTOSIS is the process by which living cells ingest or engulf other cells or particles. The phagocytic cell may be a free-living, unicellular organism, such as an amoeba, or one of the body cells, such as a leukocyte (white blood cell). The particles commonly phagocytized include bacteria, tissue cells (usually dead), protozoa, various dust particles, pigments, and other minute

foreign bodies. In the simpler forms of animal life, such as amoebae and sponges, phagocytosis is a means of feeding; in higher animals phagocytosis is chiefly a defensive reaction against infection.

To Elie Metchnikoff is due the chief credit for recognizing the importance of phagocytosis in protecting the body against infectious agents. In man and in vertebrates generally, the most effective phagocytic cells are the macrophages (large phagocytic cells) and the granular leukocytes (small phagocytic cells). The macrophages occur especially in the liver, spleen, and lymph nodes, where their function is to free the blood and lymph of bacteria and other particles. Macrophages are also found in all tissues as wandering amoeboid cells, and a cell related to the macrophage is found in the blood (*q.v.*). The smaller type of phagocyte (granular leukocyte) is carried along by the circulating blood until it reaches an area of infection, where it crawls through the blood vessel wall, being directed toward the invading bacteria by means of substances given off by the bacteria.

This directed movement is known as chemotaxis.

Before phagocytosis is accomplished, the phagocyte and particle must adhere to each other, and whether this is possible depends largely on the chemical nature of the surface of the particle. On less virulent bacteria ordinary proteins from the blood form a surface film to which leukocytes adhere, and phagocytosis follows. But virulent bacteria are ingested with more difficulty. Leukocytes, instead of adhering to them, succeed only in pushing them away. If, however, the leukocytes succeed in pushing them against a firm surface, such as the lining of a blood vessel, the bacteria may not be able to slip away and are ingested. This process is known as "surface phagocytosis." Other virulent bacteria may not be phagocytized until their surfaces are coated with peculiar globulins (proteins) formed by the body in response to the presence of that kind of bacterium. Such globulins are called antibodies, and antibodies are of great importance in establishing immunity of the body to diseases. (*See* also IMMUNITY AND IMMUNIZATION.)

The manner in which a phagocytic cell ingests a particle varies somewhat with the size of the particle. Small particles, such as bacteria or minute grains of charcoal, seem to be ingested in an instant. At one moment they appear through the microscope to be adherent to the surface of the phagocyte; at another moment they are inside it. Larger objects such as clumps of bacteria or tissue cells are phagocytized by a more prolonged response of the leukocyte. The cell flows around the object until it has been completely engulfed.

The results of phagocytosis are digestion and destruction of the particle by means of enzymes inside the phagocyte. This is the chief means by which the body gets rid of bacteria and other microorganisms. If the particle is indigestible, however, as is a grain of carbon, it eventually may be ejected by the phagocyte. Also, ingested living organisms, such as tubercle bacilli, may be resistant to the intracellular digestive enzymes and not only survive but multiply within the phagocyte. In moving about, the phagocyte may then carry such bacteria into other parts of the body and therefore actually assist in the spread of disease instead, as is more usual, of defending the body against infection.

BY COURTESY OF CHAS PFIZER & CO., INC.

PHAGOCYTOSIS OF STREPTOCOCCI BY A LEUKOCYTE, SURROUNDED BY ERYTHROCYTES

It is possible to mimic phagocytosis by means of a demonstration of nonliving models. A drop of chloroform is suspended in water and a bit of clean thread of glass is placed in contact with the chloroform. Under these conditions, the glass is not taken up by the chloroform. Then the glass thread is coated with shellac and, since the chloroform is able to spread on the shellacked surface, the drop of chloroform phagocytizes the glass thread. Finally the chloroform dissolves the shellac and then ejects the uncoated glass thread.

PHALANGER, a name applied to small to medium-sized, woolly-coated pouched mammals of the family Phalangeridae, native to Australia (where they are called opossums or possums), New Guinea and nearby islands. They have long, often prehensile tails, large claws and opposable, nailless, first hind toes. They are nocturnal in habit and feed on fruit, leaves and blossoms, though a few are insect-eaters. Several possess gliding membranes between the fore and hind limbs.

AXEL POIGNANT

PETAURUS SCIUREUS, A FLYING OPOSSUM OF THE PHALANGER FAMILY

Included among the arboreal gliding species are the flying opossums or sugar gliders, *Petaurus*, with several species on the Australian continent, the Aru Islands and New Guinea, and a parachuting form, the minute pygmy glider or feather tail (*Acrobates pygmaeus*) of eastern Australia.

The cuscuses (*Phalanger*) are arboreal animals the size of cats. The tail is prehensile. They inhabit the Solomon Islands, ranging thence to Timor and the Celebes. Nearly allied to these are the Australian forms, of which the common or brush-tailed phalanger (*Trichosurus vulpecula*), about the size of a small fox, is the best known. Others of the family include the pen-tailed phalangers (*Distoechurus*) and the long-snouted phalangers or honey possums (*Tarsipes*). The greater gliders (*Schoinobates*) and the ring-tailed opossums (*Pseudocheirus*) compose, with the koalas, the subfamily Phascolarctinae, which is sometimes elevated to a family. *See* MARSUPIAL.

PHALARIS, tyrant of Akragas (modern Agrigento) in Sicily *c.* 570–554 B.C., notorious for his cruelty, was responsible for the building of the Temple of Zeus Atabyrios in the citadel and took advantage of his position to make himself despot. Akragas seems to have prospered under his rule; its splendid planning probably belongs to his time. He fought against the Sicans and extended the territory of Akragas.

In a bronze bull, designed by Perilaus or Perillus, his victims were roasted alive, their shrieks representing the bellowing of the bull. Perilaus himself is said to have been the first victim. A bull of some kind seems historical, though probably embellished by fiction. Phalaris was overthrown by Telemachus, the ancestor of Theron (tyrant *c.* 488–472), and, it is said, was burned in his own bronze bull.

The later sophists perversely represented Phalaris as a naturally humane and cultured man. Lucian wrote two *Phalaris* speeches; the famous 148 *Letters of Phalaris* were proved by Richard Bentley (*q.v.*) to have been written by a sophist or rhetorician (possibly Adrianus of Tyre, d. *c.* A.D. 192) hundreds of years after the death of Phalaris. Before their exposure by Bentley the letters were highly thought of, *e.g.*, by Sir William Temple in his *Essay on Ancient and Modern Learning* (1692), though others, such as Politian and Erasmus, perceived that they were not by Phalaris.

For the letters *see* R. Hercher, *Epistolographi Graeci*, pp. 409–459 (1873); R. C. Jebb, *Bentley*, ch. 4–5 (1882). *See* also T. J. Dunbabin, *The Western Greeks*, ch. 10 (1948), for history.

PHALAROPE, the name for three species of shorebirds constituting the family Phalaropodidae. The lobed membranes on their toes and their denser plumage, features that distinguish them from sandpipers, enable phalaropes to swim freely. Males, which in the reproduction season are less brightly coloured than females, incubate the eggs.

The red phalarope, or grey phalarope of the British (*Phalaropus fulicarius*), and the northern phalarope, or red-necked phalarope (*Phalaropus* or *Lobipes lobatus*), nest throughout the Arctic and subarctic latitudes, while Wilson's phalarope (*Steganopus tricolor*) breeds only in North America, from British Columbia to central California and northwestern Indiana. After breeding, all the phalaropes spread southward over the oceans; many traverse the Equator, Wilson's even reaching the Falkland Islands.

(J. P. Ch.)

PHALLICISM (Phallism), a form of worship in which adoration is paid to the fertility and generative function, often symbolized by the male organ (phallus). The same principle is at the root of the nature worship of Asia Minor, in which the chief deity, the Great Mother of the Gods (*q.v.*), was the personification of the earth's fertility. Similarly in India worship is paid to divine mothers; the phallus is called *linga* or *lingam*, with the female counterpart called *yoni;* the *linga* symbolizes the generative power of Shiva (*see* Hinduism: *Gods*) and is a charm against sterility. The rites classed together as *Shakti puja* represent the adoration of the female principle (*see* Shaktism).

Phallic emblems are found in many parts of the world; for example, the serpent has been interpreted as a sexual symbol in Judeo-Christian religions (*see* Adam and Eve). The tendency, however, to identify all obelisklike stones and tree trunks, together with rites like circumcision, as remains of phallic worship has met with much criticism, and the best modern view is that phallicism never developed into an organized cult.

See also Aphrodite; Cabeiri; Dionysus; Priapus; Priapea.

PHANARIOTES, the general designation of the principal Greek families resident in the Phanar; *i.e.*, in the Greek quarter of Constantinople (Istanbul) under Turkish rule, where the ecumenical patriarchate of the Orthodox Eastern Church still has its seat. Members of these families served as dragomans (interpreters) to the Sublime Porte and to foreign embassies from 1669 and were appointed hospodars of one or other of the Danubian principalities (Moldavia and Walachia, vassal states of the Ottoman Empire) in the period 1711–1821, which is therefore known as the Phanariote period in the history of Rumania (*q.v.*). Leading Phanariote families were those of Argyropoulos, Cantacuzino, Mavrokordatos, and Ypsilantis.

See E. R. E. (Rizos Rangabé), *Livre d'or de la noblesse phanariote et des familles princières de Valachie et de Moldavie* (1904).

PHANIAS (Phainias) (fl. *c.* 300 B.C.), Greek philosopher, of Eresus on the island of Lesbos, was a pupil of Aristotle and a friend of Theophrastus, whom he joined in the Peripatetic School. He is mentioned as the author of works on logic, in which he probably followed Aristotle's doctrine; he also wrote, as Theophrastus did, on botany; and there are remains of works by him on poets, on the Socratic philosophers, and on history. His *Prytaneis of Eresus* was a history in which events in the Greek world in general were included, the chronology being determined by the series of the successive magistrates of his native place. In his *Tyrants of Sicily* he seems to have dealt with Western history against a panhellenic background. *See* also Peripatetics.

See the texts ed. by Carl Müller, *Fragmenta historicorum graecorum*, vol. ii (1848); also R. Laqueur, "Phainias," in Pauly-Wissowa, *Real-Encyclopädie der classischen Altertumswissenschaft*, vol. xix (1938).

(F. Wi.)

PHARAOH, the Hebrew form of the Egyptian *Per-a'o*, "the great house," signifying the royal palace, an epithet applied in the New Kingdom and after, as a title of respect, to the king himself (*cf.* the use of "the Sublime Porte" to designate the sultan of Turkey). In the 22nd dynasty the title was added to the king's personal name; the biblical "Pharaoh Hophra" is in accordance with contemporary native usage. The Assyrian form was *Pir'u*.

In official documents the full titulary of the Egyptian king contained no fewer than five names. The first and oldest identified him as the incarnation of the falcon-god Horus, ; it was often written inside a square called *serekh*, depicting the facade of the archaic palace. The second name, "Two Ladies," , placed him under the protection of Nekhbet and Buto, the vulture and uraeus goddesses of Upper and Lower Egypt; the third, "Golden Horus," , signified perhaps originally "Horus victorious over his enemies." The last two names, written within a ring or "cartouche," , are generally referred to as the praenomen and nomen and were the ones most commonly used; the praenomen, preceded by , "King of Upper and Lower Egypt," usually contained a reference to the king's unique relationship with the sun-god Re, while the fifth, or nomen, was preceded by "Son of Re," or by "Lord of the Two Lands." This latter name was given him at birth; the rest were conferred upon him at his coronation, when his protocol was proclaimed.

Pharaoh was referred to in narrative as "His Majesty," or "the good god" or "the sovereign," or simply by the impersonal "One went . . ." as a circumlocution of respect. In accordance with the concept of divine kingship his person was sacrosanct, and his insignia—diadems, crowns, sceptres, staves—had magic properties.

See H. Frankfort, *Kingship and the Gods* (1948); Hugo Müller, *Die formale Entwicklung der Titulatur der aegyptischen Könige*, Aegyptologische Forschungen 7 (1938). (M. S. Dr.)

PHARISEES, a Jewish sect of the second commonwealth. Its origins are obscure. According to rabbinic tradition, the Pharisees were in the direct line of transmitters of the Oral Law from Ezra and the men of the Great Sanhedrin. Their more immediate ancestors were the pietistic group of *Hasidim* who, in the middle of the 2nd century B.C., helped spearhead the Maccabean revolt (*see* Maccabees). They gradually disappeared as a distinct movement after the fall of Jerusalem in A.D. 70, only because virtually the whole Jewish people accepted their ideology.

According to Josephus, the Pharisees, in contrast with the Sadducees, believed in retribution after death and personal resurrection, and also espoused a combination of free will and predestination. Far more important, however, was the Pharisees' insistence on the binding nature of Oral Law, which, in their opinion, had been revealed to Moses simultaneously with the written Torah and had co-ordinate authority with it.

The polemical utterances in the Gospels (for instance, Matt. xxiii, 15; Mark vii, 6), apparently aimed at the more rigid faction of the house of Shammai (*q.v.*), created the image of the Pharisees as religious hypocrites—an image from which only modern research has been able to free them. *See* Jewish Sects During the Second Commonwealth; *see* also references under "Pharisees" in the Index.

See Louis Finkelstein, *The Pharisees: the Sociological Background of Their Faith*, 2nd rev. ed., 2 vol. (1940); Salo W. Baron, *A Social and Religious History of the Jews*, 2nd rev. ed., especially vol. ii, p. 35 ff., p. 342 ff., with bibliography (1952). (S. W. B.; X.)

PHARMACOLOGY. In the broadest sense, pharmacology is the study of the changes produced in living animals by chemical substances (except foods); the animals may include any species from a microorganism to man.

The term pharmacology is used sometimes, in a more restricted sense, to refer to the study of the action of drugs, that is, agents used to treat diseases. This represents the most important application of pharmacology and explains its place among the medical sciences. It is clearly distinguished from pharmacy, the art of preparing drugs for use, but is closely related to therapeutics, the application of drugs to the treatment of disease, and to toxicology, the study of poisons and poisonings; both of these may be considered to be specialized applications of pharmacology. In a

practical sense, pharmacology is the experimental science on which therapeutics is based, since the safe and effective use of drugs in the treatment of diseased patients is possible only after careful observations of their effects in the laboratory.

Origins of Pharmacology.—Attempts to use drugs to alleviate disease are as old as the history of man, but until the last century they were based mainly on superstition, magic, religion or at best on trial and error. European medicine before A.D. 1500 was characterized by rigid adherence to the medical doctrines of the ancient Greeks—principally those of Galen (*c.* A.D. 130–*c.* 200), whose prolific writings, about a hundred volumes in all, represented some original observations, many elaborate recipes for prescriptions and a great many dogmatic "explanations." The writings of Galen were accepted as absolute authority for more than a thousand years, to such an extent that original observations and experimentation were not only discouraged but often actually forbidden. The first among many successful rebels against Galenism was Paracelsus (Theophrastus Bombastus von Hohenheim, *c.* A.D. 1490–1541), a truly bombastic iconoclast who wandered through northern Europe, always in trouble with the local authorities, but overcoming the objections of his contemporaries by his therapeutic successes. He was an original thinker and daring innovator who introduced many new remedies and advocated simple prescriptions with one or a few ingredients rather than the dozens handed down from Galen.

In the next 300 years, there was a steady accumulation of information on the structure and functions of the body both in health and disease. However, therapeutics remained an "art" rather than a science, and, although the term "Pharmakologie" was used in 1692 by S. Dale in London, it meant merely the description of substances used in medicine. The pharmacopoeias (official volumes containing descriptions and outlining standards for drugs) included such remedies as dried vipers, foxes' lungs, and moss from the heads of criminals who had been hanged in chains, along with some herbs of real value. The concept of systematic laboratory investigation of drug action did not arise until about 1850; it was not until then that the public was made aware of the necessity for animal experimentation (by François Magendie, the French physiologist). Observations of the action of chemicals on the animal body became possible only after the new physiologists developed sensitive methods for the measurement and recording of changes in the function of the body. An equally important contribution was the striking development of chemistry. It was difficult to experiment with the crude drugs and extracts available because their potency varied from one batch to another. The situation began to change during the first half of the 19th century, when the new chemists in France and Germany isolated many active substances—morphine, strychnine, atropine, quinine and many others —from their crude plant sources.

As these pure chemicals became available (and later, as thousands of new chemical compounds were synthesized in the rapidly expanding German dye industry), more and more studies of drug action were made. The first students of pharmacology were physiologists who became curious about the effects of the substances on heart rate, respiration or other of the physiological functions they were studying—or who used the compounds as tools to study physiological problems. The first laboratory devoted exclusively to experimental pharmacology was that of Rudolph Buchheim at Dorpat (now Tartu, Est.) in 1846–47; he contributed the idea that the effects of drugs on the body should be explained as well as described.

Pharmacology as an independent experimental science was really founded and firmly established by the German Oswald Schmiederberg (1838–1921). He defined its purpose—the study of the damage brought about in living organisms by chemically acting substances (except foods, whether used for therapeutic purposes or not). He wrote a textbook of pharmacology, helped to found the first journal devoted to reports of pharmacological experiments, and, most important, headed a school at Strasbourg which attracted students from all over the world. His school was the nucleus from which independent departments of pharmacology were established in universities all over the world.

Methods and Purposes of Pharmacology.—The work of pharmacologists is closely related to that of other biological scientists. In order to understand the changes produced in living animals, pharmacologists must understand, and be able to measure, the normal operations of the animal body—physiology. They must also understand pathology, the study of changes in structure and function resulting from injury or disease. The recognition and description of such changes may require not only gross observations on living animals but also microscopic examination of tissues or cells, or chemical determinations on body fluids or excretions. If pharmacologists study the effectiveness of such drugs as antiseptics or antibiotics, they must use the concepts and methods of bacteriology. If they are attempting to find the ingredients responsible for the actions of crude plant drugs, they may find themselves involved in both chemistry and botany. Their work is often related to biochemistry (chemistry of living things), since they study effects of foreign substances on cells or chemical systems of the body.

During the earlier years of the new science, its workers became aware that a relation exists between the chemical structure of a compound and the effects it produces in the body. Since that time, increasing emphasis has been placed on this phase of pharmacology and many studies describe the changes in action resulting from small changes in the chemical structure of the drug. Since most agents of medical interest are organic chemicals (complex structures containing carbon atoms), pharmacologists who engage in such studies must have an understanding of organic chemistry.

The development of atomic resources for peacetime uses after World War II brought pharmacologists into a new area of investigation. One of the major problems of pharmacology has always been the difficulty of determining the fate of foreign compounds in the body. The doses of most potent drugs and poisons are small, and when they are distributed in large volumes of body fluids, they become almost impossible to detect or measure by ordinary chemical means. However, it is highly desirable to trace minute amounts of the compounds in the bloodstream or in the organs of the body in order to determine whether they are concentrated in any organs or cells and to establish how long they remain and how they are excreted. This was made possible by the availability for scientific investigation of radioactive isotopes (chemical elements having almost exactly the same chemical properties as the normal, but capable of being detected by Geiger counters or similar instruments). Since 1945, pharmacologists have been tracing the passage of some compounds through the body by incorporating radioactive atoms into the compounds they wish to study. The small amounts of radioactivity are not harmful to the animals; in fact, in some carefully controlled studies such determinations have been made on human volunteers. The tracer compounds are usually synthesized chemically, but where this is difficult or impossible, they have been prepared by exposing plant or animal sources to radioactive materials in such a way that radioactive atoms are incorporated into the desired compounds as the living plant or animal manufactures them; the radioactive substances are then isolated and purified to be used in experiments.

In general, pharmacologic investigations are directed toward describing completely the interaction between the body and the drug. This includes describing fully the sequence of physiological changes that occur and describing what happens to the drug itself. It includes also explanations for the observed changes, at least in terms of physiology, and preferably in terms of chemistry or physics. Chemical explanations of mechanisms of action have been established for a number of chemical substances. These explanations have much more than academic interest; they tend to increase our knowledge of physiology and other biological sciences; they make it possible to use drugs more effectively; and by showing what characteristics are necessary for therapeutic action they stimulate the search for more effective new agents, without the undesirable side effects possessed by many available drugs. Such information is also sought for poisonous compounds used in the home (bleaches, insecticides, etc.), in industry or in agriculture (pesticides) in order to minimize health hazards (see *Pharmacology in Public Health*, below).

Pharmacology in Medical Education and Research.—Since pharmacology is a part of the curriculums of medicine, dentistry, veterinary medicine and pharmacy, departments of pharmacology are usually associated with educational institutions in these fields; the programs usually include training and study at the graduate level as well as the required courses of instruction. Such departments, especially in medical schools, are traditionally devoted to the study of basic problems in pharmacology and to the application of basic principles to the solution of specific medical problems. Research in pharmacology is conducted also in many hospitals and foundations, either publicly or privately supported.

Pharmacology in the Drug Industry.—Important basic research is carried out in the research laboratories of pharmaceutical and chemical companies. After 1930, this area of pharmacological research expanded rapidly, particularly in the United States. The utilization of the financial resources of industry, together with the contributions of universities, hospitals and foundations, resulted in the solution of many complicated problems in a surprisingly short time. Many new therapeutic agents were developed (*e.g.*, sulfa drugs, antibiotics, cortisone, "tranquilizing" drugs and many others), and a great body of fundamental knowledge was accumulated.

The work of pharmacologists in industry deals also with the exhaustive tests that must be made before promising new drugs can be introduced into medical use. Detailed observations of effects on all systems and organs of experimental animals are necessary before the physician can accurately predict effects of the drug on his patients, but their principal purpose is to disclose any potential toxicity to man. It must be emphasized that, except under unusual circumstances, the pharmacologist does not test the effects of drugs in patients; this is done only after complete tests on animals and is usually conducted by physicians to determine the clinical effectiveness of new drugs.

Constant testing is also required for the routine control and standardization of drug products. Those which contain only pure active ingredients can be tested by chemical means, but a few still remain that consist of relatively crude mixtures of plant or animal products (digitalis and pituitary, for example). These can be standardized (adjusted to standard strength) only after the pharmacological potency of each batch is determined by comparing its effect on some species of animal with the effect of a standard sample of drug. This process of testing is known as bioassay, and the entire process of standardization is known as biological standardization.

Pharmacology in Public Health.—The public welfare is obviously dependent on adequate pharmacological examinations of new products, but the development of new compounds and new processes throughout industry is also associated with potential health hazards for workers. The study of such hazards is termed industrial toxicology and the concepts and experimental methods are those of pharmacology, adapted for special conditions. Another application of pharmacology (or, more specifically, of toxicology) is in the study of the poisons used in agriculture to control plant pests and animal parasites. Here pharmacological or toxicological studies are undertaken to discover how the agents act to destroy pests; this makes it possible to use the agents more efficiently, and to develop more satisfactory new ones. Attention is also focused on the evaluation of potential health hazards and on the development of antidotes and methods of treatment to be used in cases of accidental poisoning. *See* also PHARMACY; PHARMACOPOEIA. (V. E.)

PHARMACOPOEIA, a book published by a government, or otherwise under official sanction, to provide, for a specific political area, standards of identity, quality and strength for those medicinals which represent the best practice and teaching of medicine. The primary function of a pharmacopoeia is to describe each drug on the approved list in such a way that whenever dispensed it meets the standards of quality and strength established for it. The provisions of the pharmacopoeia in force (*i.e.*, the one that is "official") are binding upon all who produce drugs and those who dispense them. The pharmacopoeia is a fundamental safeguard to public health.

The task of compiling most pharmacopoeias is carried out without compensation by experts in the professions of medicine, chemistry and pharmacy at the request of the agency undertaking the compilation, usually that responsible for matters of public welfare. Most programs are financed from government funds, but the *British Pharmacopœia* and the *United States Pharmacopeia* are written by private, nonprofit organizations with the sanction of their respective governments. In the case of these pharmacopoeias, the proceeds of their sale support the work of revision.

The oldest record in the form of a pharmacopoeia is a stone tablet of ancient Babylonia, believed to have been inscribed about 1700 B.C. The first true pharmacopoeia to appear in Europe was the Florentine *Nuovo Receptaris* (1498). The Danish Pharmacopoeia (established 1772) is the oldest in continued existence. The following countries established pharmacopoeias (the dates indicate the latest edition or [italics] supplement or reprinting): Argentina (1957), Austria (1960), Belgium (1930, *1953*), Brazil (1959), Chile (1941), China (1953), Czechoslovakia (1954, *1959*), Denmark (1948, *1954*), Egypt (1953), Finland (1956), France (1949, *1954*), Germany (1926, *1951*), Greece (1924), Hungary (1954, *1958*), India (1955), Italy (1940), Japan (1961), Mexico (1952), Netherlands (1958), Norway (1939, *1953*), Paraguay (1945), Poland (1954, *1962*), Portugal (1946), Rumania (1956), Spain (1954), Sweden (1946), Switzerland (1933, *1958*), Turkey (1948), U.S.S.R. (1961), United Kingdom (1963), United States (1960, *1962*), Venezuela (1942), Yugoslavia (1951).

Most countries not having a national pharmacopoeia adopted that of one or more other nations or in some cases adopted the international pharmacopoeia (*see* below).

The pharmacopoeial standards form the basis for enforcement of laws on the quality of drugs made available within the country concerned. Thus, the standards established have a vital bearing on the level of public health and the practice both of medicine and pharmacy. Actual enforcement of the standards is generally a function of an agency separate from that which creates them, but there are exceptions to this, notably in Canada, where the same department both establishes and enforces the standards. Enforcement involves collection and analysis of drug samples purporting to be of pharmacopoeial quality; when the analytical findings do not substantiate the label claim, legal action may be taken. This form of control varies greatly from one country to another. Where the central government is strong, the control is generally on a uniform national scale, as in the Americas and most of Europe. Where the local government is strong, as in the case of the cantons of Switzerland, enforcement is mainly on a local scale. These inter- and intra-national differences result in variations in the strength and quality of drugs, which cause confusion for both travelers and medical practitioners and are not in the best interests of public health. Travelers benefit especially from uniform drug standards. For example, a diabetic who travels must depend largely upon local sources for the insulin that makes the difference for him between good health and dangerous illness. Insulin is prepared from the pancreatic glands of cattle and its potency must be standardized by assays on rabbits or mice. Furthermore, it deteriorates if not kept cold. However, thanks to the acceptance of uniform pharmacopoeial standards, good insulin is available almost everywhere.

International Pharmacopoeia.—Efforts to eliminate international differences in drug standards date to 1865, but the first practical move was made in 1902 by the Belgian government in sponsoring an international conference in Brussels. This resulted in the Brussels agreement of 1906, which proposed uniform nomenclature and standards of strength for many important drugs, particularly those which were being dispensed in the form of tinctures and infusions. A second conference in 1925 went still further toward establishing uniformity in pharmacopoeial standards among nations. These agreements were limited in scope, since they applied to only a few of the drugs in use.

The problem became more acute with the increase in international travel and in international trade in medicinal products after 1925, and received the attention of the Health Organization of the League of Nations, which created a Technical Commission of

Pharmacopoeial Experts. The original seven-member group undertook to prepare an international pharmacopoeia, but this was interrupted when the League went out of existence. However, the work was resumed almost immediately upon creation of the World Health organization, a specialized agency of the United Nations which is the successor to the Health Organization of the League. The newly formed Expert Committee on the Unification of Pharmacopoeias (which later became the Expert Committee on the International Pharmacopoeia and Pharmaceutical Preparations) succeeded in compiling the first volume of the *Pharmacopoea Internationalis* for publication in 1951. A second, complementary volume appeared in 1955, and a supplement was added in 1958. The WHO published the texts in English, French and Spanish, but translations into German and Japanese were undertaken privately under WHO authority. The WHO planned to revise the standards periodically toward the end of providing model specifications for all of the important drugs.

The *Pharmacopoea Internationalis* was put forward by the WHO only as a recommendation aimed to minimize or eliminate entirely variations among national pharmacopoeial standards. Some nations among those without their own pharmacopoeia, for example, Ethiopia and Israel, made the international pharmacopoeia official for use within their borders.

The four Scandinavian countries and Iceland provided a notable example of international co-operation toward uniformity in drug standards. Jointly, they formed the Scandinavian Pharmacopoeial council, which laid the foundation for publication of a single pharmacopoeia in four languages (Danish, Finnish, Norwegian and Swedish) that supersedes the existing national pharmacopoeias of those countries as the binding authority on the identity, quality and strength of drugs.

PHARMACUS, the title given in ancient Greek cult to a kind of human scapegoat used in certain state rituals. It is first mentioned by the 6th-century Ionian poet Hipponax in describing a ritual at Colophon in Lydia and is known also in Abdera (Thrace) and Massilia (modern Marseilles). In Athens a man and woman were selected as scapegoats each year. At the festival of the Thargelia (*q.v.*) in May or June, they were feasted, led round the town, beaten with green twigs, and driven out. The accounts sometimes suggest that they were killed with stones instead of being simply driven out of the country. The custom was meant to rid the place annually of ill luck.

See M. P. Nilsson, *Geschichte der griechischen Religion*, 2nd ed., vol. I, pp. 107–110 (1955). (H. W. PA.)

PHARMACY is the science and art concerned with the collection, preparation and standardization of drugs. Its scope includes the cultivation of plants that are used as drugs and the synthesis of chemical compounds of medicinal value. It further includes the analysis and standardization of medicinal agents. The pharmacist is responsible for the manufacture of the dosage forms of drugs, such as tablets, capsules and sterile solutions for injection. As a dispensing pharmacist, he compounds physicians' prescriptions for drugs. Pharmacology (*q.v.*) is the science that embraces all knowledge of drugs with special reference to their mechanism of action in the treatment of disease. Obviously this broad science has many subdivisions, such as toxicology (the study of poisons) and therapeutics (the use of drugs in the treatment of disease). Pharmacy, according to the foregoing description, is one of the subdivisions or specialties of pharmacology.

Historical Development.—The beginnings of pharmacy are of extremely ancient origin. When early man expressed a juice from a succulent leaf to apply to a wound he was practising this ancient art. In the book of Exodus, Moses was directed by the Lord to prepare "an ointment compound after the art of the apothecary." In the Greek legend, Asclepius, the god of the healing art, delegated to the beautiful Hygieia the duty of compounding his remedies. She was his apothecary or pharmacist. The physician-priests of Egypt were divided into two classes, those who visited the sick and those who remained in the temple and prepared the remedies for the patients.

In ancient Greece the art of healing recognized a separation between the duties of the physician and those of the pharmacist, and this separation prevailed also among the Roman practitioners. During the middle ages in Europe the separation of the two groups became less distinct. Many physicians undertook the preparation of their own medicines. The Moorish influence in Europe brought about the practice of separate duties for the pharmacist and physician again. The trend of specialization is exemplified by a law enacted by the city council of Bruges, Belg., in 1683, forbidding physicians to prepare their own remedies.

The distinct role of the pharmacist as separate from that of the physician is evidenced by the establishment of the office of apothecary general in the army of France during the middle of the 18th century. In America, Benjamin Franklin took an important step in keeping the two professions separated when he appointed an apothecary to the Pennsylvania hospital.

Education.—The history of pharmaceutical education has followed in the wake of medical education. As the training of the physician underwent the change from the apprenticeship system to formal educational courses, so did the training of the pharmacist. The first college of pharmacy was founded in the United States in 1821 and is now known as the Philadelphia College of Pharmacy and Science. Other institutes and colleges were established in the U. S., Great Britain and continental Europe. Later many universities organized schools and colleges of pharmacy within their courses of instruction. Colleges of pharmacy as independent organizations or as schools of universities operate in most countries of the world.

The course of instruction leading to the degree in pharmacy (bachelor of science in pharmacy) extends over four or five academic years. Many institutions, however, offer graduate courses in pharmacy and cognate sciences leading to the degrees of master of science and doctor of philosophy. These advanced courses are especially intended for those who are preparing for careers in research, manufacturing or teaching in the field of pharmacy.

It is clear that since the medication of the sick with drugs encompasses a wide field of knowledge in the biological and physical sciences, an understanding of these sciences is necessary for an adequate pharmaceutical training. The basic four-year curriculum in the colleges of pharmacy of the United States embraces physics, chemistry, biology, bacteriology, physiology, pharmacology and many other specialized courses such as dispensing pharmacy. In addition, subjects of a general educational character such as languages and mathematics are included. As the pharmacist is engaged in a business as well as a profession, special training is provided in merchandising, accountancy and pharmaceutical jurisprudence. After 1960 one year of college work in addition to high school was required for entrance to colleges of pharmacy in the United States.

Legislation.—Before he is permitted to practise pharmacy, an applicant must be qualified by graduation from a recognized college of pharmacy, meet specific requirements for experience and pass an examination conducted by a board of pharmacy appointed by the government. The passing of this board examination confers upon the person the legal right to practise pharmacy. In the United States he is then designated a registered pharmacist.

The pharmacy laws include the regulations for the practice of pharmacy, the sale of poisons, the dispensing of narcotics and the sale and labeling of dangerous drugs. The pharmacist sells and dispenses drugs within the provisions of the food and drug laws of the country in which he practises. These laws recognize the national pharmacopoeia as the standard for drugs (*see* PHARMACOPOEIA). The pharmacopoeias of the different nations are compiled and published according to the respective legal national procedures. The World Health Organization of the United Na-

tions published the first volume of the *Pharmacopoea Internationalis* in 1951. Its purpose is to standardize, as far as possible, the medication with drugs throughout the world. Furthermore, the *Pharmacopoea Internationalis* provides standards for drugs for smaller nations that have no national pharmacopoeia.

Organizations.—There are numerous national and international organizations of pharmacists. In Britain the Pharmaceutical Society of Great Britain, established in 1841, is typical of the pharmaceutical organizations. In the United States the American Pharmaceutical association, established in 1852, is a society that embraces all pharmaceutical interests. Some of the other organizations in the United States are the American Drug Manufacturers' association, the Federal Wholesale Druggists' association and the National Association of Retail Druggists. Among the international societies is the Fédération Internationale Pharmaceutique, founded in 1912 and supported by 35 national societies, for the advancement of the professional and scientific interests of pharmacy. The Pan American Congress of Biochemistry and Pharmacy includes the pharmaceutical societies in the various countries in the western hemisphere.

There are also other international societies in which history, teaching and the military aspects of pharmacy are given special emphasis.

Research.—Pharmaceutical research is conducted mainly in the schools of pharmacy and in the laboratories of the pharmaceutical manufacturing houses. It embraces the organic chemical synthesis of new chemical agents for use as drugs and is also concerned with the isolation and purification of plant constituents that might be useful as drugs. Research in pharmacy also includes methods for assay and standardization of medicinal agents. These phases of research in pharmacy are primarily an application of the science of chemistry to drug products, but the pharmacist also engages in research that is peculiar to the profession. This research involves formulation of dosage forms of medicaments, a study of their palatibility, methods of standardization and their stability. The researches of pharmacy are usually published in journals, such as the *Journal of Pharmacy and Pharmacology* (London), the *Journals* of the American Pharmaceutical association (Scientific Edition and Practical Edition) (Washington), the *American Journal of Pharmacy* (Philadelphia) and the *Pharmaceutica Acta Helvetiae* (Zürich). *See* also APOTHECARY; PHARMACOLOGY; PHARMACOPOEIA.

PHARNABAZUS (5th–4th century B.C.), Persian soldier and statesman, was hereditary satrap of Dascylitis under Darius II and Artaxerxes II. In the war with Athens, which began in 413 B.C., he supported Spartan operations in the Hellespont. When war broke out with Sparta in 400 B.C. he persuaded Artaxerxes to organize a naval counterstroke and with the help of Conon and Evagoras of Salamis raised a fleet in Cyprus. While the naval offensive was in preparation, he was hard pressed in Phrygia by the Spartan king Agesilaus, but in 394 the Persian navy, jointly commanded by himself and Conon, completely destroyed the Spartan fleet off Cnidus and gained the mastery of the Aegean. In 393 Pharnabazus accompanied the fleet to the Greek coast and gave support to the Greek enemies of Sparta; he provided funds and allowed Conon to use his crews for the rebuilding of the "long walls" at Athens. When in 388 the revival of Athenian imperialist ambitions led Artaxerxes to conclude peace and enter into an alliance with Sparta, Pharnabazus, as the chief opponent of Sparta, was recalled with honour from his command. In 385 he was one of the generals in the unsuccessful attack on Egypt. In 373, after years of preparation, he led a second expedition against Egypt but failed to take Memphis and was eventually forced by the inundation to abandon the campaign. His failure was partly due to his distrust of Iphicrates, leader of the Greek mercenaries. When Pharnabazus died is not known. (J. M. M.-R.)

PHARSALUS, BATTLE OF (48 B.C.), the decisive victory of Julius Caesar (*q.v.*) over Pompey. When Caesar disengaged himself from Dyrrachium and marched to Thessaly, Pompey followed. The two armies made contact somewhere near the modern town of Farsala in the *nomos* of Larissa, Greece, at a site which cannot be established with certainty. Pompey camped on higher ground which would favour his chances if a battle ensued. After some days Caesar, who had failed to provoke Pompey to fight, decided to move off, but as he was starting he saw that the Pompeian army was drawn up for battle; he decided to stay and fight (Aug. 9 by the uncorrected Roman calendar, in fact June 6). Whereas Caesar had 80 cohorts or 22,000 men, Pompey had 110 cohorts which Caesar (probably with exaggeration) assessed at 45,000 men. Further, Pompey trusted his cavalry and its commander, Labienus. He massed the main force of his cavalry on his left wing, hoping to outflank and envelop Caesar's right. Realizing the danger, Caesar hoped to thwart the attack by detaching eight cohorts from his third line (which he intended to hold back as a reserve) and placing them obliquely behind the cavalry on his right wing. His main infantry line was drawn up in the usual three lines of cohorts. Pompey ordered his men to await the enemy's attack, but Caesar's veteran army did not fall into the trap of arriving exhausted. Without orders they halted halfway in their advance, then after recovering their breath they charged and hurled their *pila*. Pompey's cavalry drove back Caesar's cavalry, only to find themselves faced by Caesar's fourth line of eight cohorts, who used their *pila* as stabbing spears instead of as javelins, against the horses and the men's legs and faces. Pompey's cavalry turned and fled. While the eight cohorts outflanked Pompey's infantry, then locked in battle, Caesar threw in his reserve third line. Pompey's legions broke; he himself fled to Larissa. About 24,000 Pompeians surrendered; the rest were dead or in flight. When Caesar, whose casualties were less than 250, surveyed the stricken field and the dead optimates, he cried, "They would have it so" (*"Hoc voluerunt"*). The battle is described in book vii of the *Bellum civile* of Lucan.

PHARYNX: *see* THROAT; THROAT, DISEASES OF.

PHASE EQUILIBRIA. Most substances are capable of existing in at least three forms or states of aggregation, namely the solid state, the liquid state and the vapour state. Water is a familiar example. These forms, differing in internal structure and in physical properties such as density, mobility, refractive index and heat content, constitute various phases of the substance. If a substance exhibits more than one crystalline form, as does sulfur, each of its polymorphic varieties is a distinct solid phase of the substance. The number of possible phases in a system containing more than one substance is greater, including solutions in both the liquid and solid states and other phases that are, in general, chemical compounds resulting from the chemical combination and interaction of the components.

The materials of nature and of technology are either homogeneous (*i.e.*, consisting of a single phase) or heterogeneous (*i.e.*, polyphasic) systems. Ice is a single phase; a sample of water consisting of some liquid with its vapour is in two phases; a piece of granite generally contains three phases, being essentially a conglomerate of pieces of quartz, mica and feldspar; brass is a single phase, *i.e.*, a solid solution of zinc in copper; and ordinary cast iron is an intimate mixture of at least two solid phases. Each phase, although it may be present in separate pieces, is considered to be one homogeneous kind of matter. The phase is distinct in structure, though not always in chemical composition, from the other phases of the heterogeneous sample and is mechanically separable from them.

The conditions for the coexistence at equilibrium of various

combinations of the possible phases of a system and for their formation and transformations, as controlled by variations in pressure, temperature and composition, constitute the subject of phase equilibria. The principles of phase equilibria find application in the study of structure and constitution of alloys, in practical problems of metallurgy, in the ceramics and glass industries, in the geological interpretation of minerals, in the study and utilization of salt deposits, and in general in problems of physical and chemical separations such as distillation, crystallization and extraction. The most useful and general principle underlying the treatment and representation of all phase equilibria is known as the phase rule, which was deduced by Josiah Willard Gibbs (*q.v.*) in his papers on thermodynamics (1873–78). The realization of the practical importance and universal applicability of the law is due principally to H. W. Bakhuis Roozeboom, whose treatise, *Die heterogenen Gleichgewichte vom Standpunkte der Phasenlehre* (1901–18), became the classical reference in the field.

The phase rule relates the number of components (α), the number of phases (β) and the number of degrees of freedom (*i.e.*, the variance [F]) in a system in interphase equilibrium. The system is subject only to changes in pressure, temperature and composition (proportions of its components). The equilibrium between liquid and vapour for pure water (one component) has a variance of one, *i.e.*, the system is univariant inasmuch as the vapour pressure is a unique function of the temperature, and these are the only intensive variables. (An intensive variable is one, such as pressure and temperature, that is not a function of the magnitude of the phase. Pressure and temperature are intensive variables, mass and volume are not; they are said to be extensive. *See* THERMODYNAMICS.) Arbitrary specification of one fixes the other. A liquid-vapour equilibrium for a binary solution (that is, one containing two components, such as acetone and water) is bivariant; it has two degrees of freedom. Of the four variable quantities—pressure, temperature, liquid composition, vapour composition—one may, within the range allowed by the system, arbitrarily choose the values of any two without disturbing the number or nature of the phases in equilibrium.

In other words, it is necessary and sufficient to specify two of the four quantities in order to fix the other two, and hence in order to specify the system completely with respect to its intensive variables. If this system is cooled until pure ice appears as a third phase the variance is reduced to one, for the specification of any one of the several variables already mentioned suffices to determine the system completely. At equilibrium these intensive variables are independent of the masses, actual and relative, of the phases involved. The freezing point of ice, for example, does not depend on the amount of ice being melted. Likewise, the solubility of a salt (*i.e.*, its concentration in its saturated solution) is independent of the amount of solid salt present in excess.

The number of components in a system is usually evident from the mode of preparation of the system, as for an alloy or an alcohol-water solution. It is not, however, simply the number of chemical species in a system. For example, water, a single substance, may exist in various states of molecular aggregation in its various phases; it may exist in part in the form of ions and it may dissociate at high temperature into hydrogen and oxygen. But as long as all these species are in equilibrium with each other in each phase, and provided that the total composition of each phase is analytically H_2O so that it is not necessary to state the proportions of two or more substances making up the system, only a single component is involved. The number of components is the smallest number of independently variable substances required to account for the composition of all the phases of the system. In the heterogeneous equilibrium between solid $CaCO_3$ and its dissociation products, solid CaO and CO_2 gas, there are three distinct species but only two components since CaO and CO_2 together give the composition of $CaCO_3$. But one may also choose $CaCO_3$ as one of the components if the quantity of the other (either CaO or CO_2) is allowed to have negative values in expressing composition. Similarly the four substances in the equilibrium $BaSO_4 + Na_2CO_3 \rightleftharpoons BaCO_3 + Na_2SO_4$ involve only three components, since any three can be used to express the composition of the fourth; thus $BaCO_3 = BaSO_4 + Na_2CO_3 - Na_2SO_4$. The choice of the nature of the components may be one of convenience, but their number, defined as the sufficient minimum, is fixed.

The phase rule states that for a system in equilibrium

$$F = \alpha - \beta + 2$$

The maximum number of phases possible at equilibrium is therefore $\alpha + 2$. This maximum number occurs only when the system is invariant, *i.e.*, when $F = 0$. The conditions of pressure, temperature and phase compositions are then uniquely fixed by the nature of the system itself. The pressure, for example, may be arbitrarily varied only if the equilibrium is at least univariant with the number of phases not greater than $\alpha + 1$. In the formation of certain mineral deposits, moreover, it must be assumed that the total process has taken place over a range of both pressure and temperature; the number of coexisting phases in the accompanying bivariant equilibria then cannot exceed the number of components. Such restrictions, however, apply only to systems in true heterogeneous equilibrium. Because of the very number of phases present, consequently, many materials (for example, certain metamorphic mineral assemblages, certain salt deposits produced by evaporation of sea water and some alloys undergoing various sequences of thermal and mechanical treatment in their preparation and use) would thus seem to be beyond treatment by the phase rule because they are obviously not in equilibrium. Nevertheless it is only by reference to principles of phase equilibria combined with kinetics of chemical reactions and phase transformations, as they must apply to the possible relations in these materials, backward and forward in time through changes of pressure and temperature, that one can interpret their formation or origin and predict their future behaviour in their inevitable course toward equilibrium.

The phase rule, moreover, is also limited in its application to the behaviour of systems assumed to be subject only to variations in pressure, temperature and proportions of components, and free from influences of electrical and magnetic fields, of gravitational effects and of surface energy effects. The effect of gravity, which can practically never be eliminated, is altogether negligible for almost all applications of the phase rule. Surface effects, on the other hand, are extremely important in systems containing finely divided colloidal substances or other materials possessing large surfaces, such as adsorbents and catalysts. The interphase relations in these cases are not covered by the ordinary phase rule, which applies to equilibrium of bulk phases.

One-Component Systems.—Since pressure and temperature are the only variables to be considered, the phase diagram of a single substance is represented with two co-ordinates, as in fig. 1.

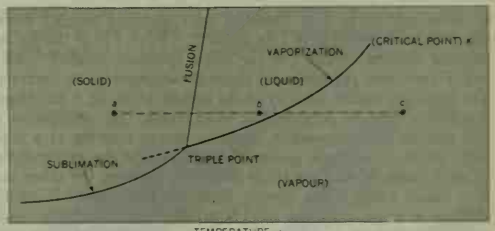

FIG. 1.—PHASE EQUILIBRIA FOR THE SOLID, LIQUID AND VAPOUR STATES OF A SUBSTANCE

Each of the three areas shows the range of pressure and temperature in which the substance exists as a single phase, in bivariant equilibrium. Both pressure and temperature of a sample of the vapour, for example, may be varied without change of phase, and both must be specified in order to fix the properties of the vapour; these properties depend solely on these variables. A line between two areas represents the univariant conditions of pressure and temperature for the equilibrium coexistence of two phases; these are phase boundaries or phase transition curves, specifically the sublimation curve for solid-vapour, the fusion curve for solid-liquid and the vaporization curve for liquid-vapour equilibrium.

These three curves intersect at the triple point, which shows the single values of the pressure and the temperature for the coexistence of the three phases.

For the co-ordinates at point *a* the substance is entirely solid. As the temperature is raised at constant pressure, the properties of the phase, such as heat content, refractive index and density, change gradually but the phase remains a single phase until the fusion curve is reached. Here the temperature remains constant as heat is absorbed and as solid melts to liquid. The system does not leave the transition curve until the solid is consumed. The sample is then entirely liquid as shown, for example, at point *b*, until the temperature of the vaporization curve is reached. Now vapour begins to form with absorption of heat, and the temperature remains constant until all of the liquid has disappeared and only vapour remains. The temperature may now increase further to a point such as *c*. The boiling of a pure liquid in the open, under constant atmospheric pressure, is thus seen to be a source of constant temperature (about 100° C. for water at 1 atm.). The two-phase equilibrium thus persists at constant temperature through isobaric introduction of heat, which is compensated by phase transitions leading to volume changes. Similarly, isothermal expansion of the system liquid-vapour merely causes some liquid to vaporize, with change in total heat content, while the pressure, depending solely on temperature, remains constant until the liquid is consumed. The triple point is characterized by unique values of pressure and temperature and hence of all the specific properties of each of the three phases. Neither a change in volume nor the addition or removal of heat can cause a change in any of the intensive variables because the applied stresses are completely compensated, at equilibrium, by changes in the relative amounts of the phases until one of them is consumed, leaving a univariant two-phase system.

The ice-liquid-vapour triple point for pure (and isolated) water is at 4.58 mm. and +0.0100° C. In the open air at 1 atm. pressure, however, the constant temperature obtained from the equilibrium of ice and liquid water is, by definition, zero on the Celsius or centigrade scale. The difference in the temperature results from the effect of the increased pressure in lowering the melting point of ice and a further slight effect of air dissolved in the liquid.

With increasing temperature at constant pressure, transitions occur from phases of lower to phases of higher heat content. With increasing pressure at constant temperature, transitions occur to phases of higher density. The slope of a transition curve at any point is given by the Clapeyron-Clausius equation:

$$\left(\frac{dP}{dT}\right)_{1\to 2} = \frac{\Delta H_{1\to 2}}{T(V_2 - V_1)}$$

in which ΔH is the heat absorbed (per specified weight) during the transition from phase 1 to phase 2; $(V_2 - V_1)$ is the accompanying volume change (of the same specified weight); and P and T represent pressure and absolute temperature respectively. The equation applies not only to the transitions in fig. 1 but also to transitions between polymorphic solid forms. In consequence of this relation the intersection of three curves meeting at a triple point involves no angle greater than 180°, and the extrapolation of each curve beyond the triple point lies between the other two. The fusion curve rising steeply from the triple point is usually positive in slope, since the solid is usually denser than the liquid, as illustrated in fig. 1. In the unusual case of water and a few other substances, the liquid is denser than the solid and the slope is negative.

For the relative slopes of the sublimation and vaporization curves at the triple point (with the same pressure and temperature for all three phases), the volume change is large and practically equal for both transitions, but the sublimation curve is steeper since the heat of sublimation exceeds the heat of vaporization by the heat of fusion. The dashed extension of the vaporization curve of fig. 1 represents the liquid-vapour system supercooled below the freezing point without crystallization, as is possible, at least temporarily, in the absence of dust, *i.e.*, of nuclei for crystal formation, and in the absence of mechanical disturbance. Although continuing to fall, the vapour pressure of the supercooled liquid is higher than that of the solid (on the sublimation curve) at corresponding temperatures. The supercooled liquid is said to be metastable with respect to the solid; the liquid eventually, especially if disturbed, transforms to the stable solid phase.

The actual physical and chemical properties are not directly indicated on the phase diagram, but they are nevertheless completely determined by the information in the diagram—pressure, temperature and phase compositions. The density of a pure vapour, for example, depends only upon its pressure and temperature.

In a closed vessel containing pure water in the forms of liquid and vapour at 25° C. the liquid is very much denser than its saturated vapour. With increasing temperature the vapour pressure rises, the liquid becomes less dense while the equilibrium vapour becomes denser and the two coexisting phases approach each other in all properties. They finally become identical, merging as one "fluid" phase at the critical point of the substance. This is shown as point *K* in fig. 1, marking the end of the vaporization curve; beyond this point the distinction between liquid and vapour has vanished. The critical constants for water are 218.3 atm. and 374.2° C. Its density at the critical point is 0.32 g. per cubic centimeter.

When a substance exists in more than one crystalline form, the number of phase areas in the equilibrium diagram increases. So also does the number of transition curves and triple points. In the case of water the polymorphism of ice is manifested only under high pressure. The temperature of equilibrium between ordinary ice (ice I) and liquid water falls with increasing pressure until, at triple point *a* of fig. 2 at 2,045 atm. and −22° C., a different crystalline variety of ice appears (ice III). Five distinct high-pressure forms of ice have been identified (II, III, V, VI, VII) with fields of stability as shown in fig. 2. Ice VII, requiring 21,700 atm. for its formation, is in equilibrium with liquid only at 81.6° C. (triple point *b*) and above. High-pressure polymorphism is exhibited frequently by both elements and compounds.

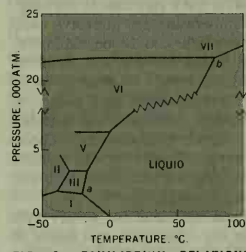

FIG. 2.—EQUILIBRIUM RELATIONS FOR THE HIGH-PRESSURE FORMS OF ICE

Of the two crystalline forms of carbon—graphite and diamond—the first is stable under ordinary conditions. Diamond is a high-pressure form corresponding somewhat to ice III in fig. 2. Once formed, naturally or artificially, under appropriate values of pressure and temperature, the diamond structure persists indefinitely at ordinary conditions because the rate of transformation to stable graphite is immeasurably slow. Boron nitride (BN), which is closely related to carbon in electronic structure, shows a polymorphism parallel to that of carbon; *i.e.*, it displays a hexagonal form with a layered structure like graphite and a very hard cubic form, obtainable at high pressure, similar to diamond.

The crystalline polymorphism of sulfur is observed, in contrast to the high-pressure relations of fig. 2, in the presence of the vapour phase, either pure or in open air. (Polymorphism of an element is usually called allotropy.) Rhombic sulfur, which is stable at low temperature, transforms at 95.5° C. to monoclinic sulfur, the form stable to the melting point. Each form has its own sublimation curve and the two curves intersect at the transition point (triple point *a* in fig. 3), where the two solids can coexist at equilib-

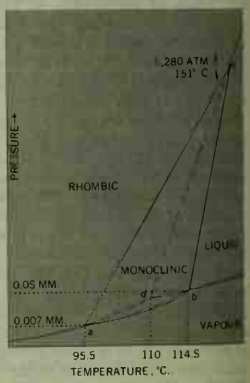

FIG. 3.—EQUILIBRIUM DIAGRAM FOR SULFUR (NOT TO SCALE)

rium in presence of vapour. Such polymorphism, with a transition point under the vapour pressure of the system, is known as enantiotropy. The triple point *b* represents stable equilibrium of liquid + vapour + monoclinic sulfur; the range of stability of this solid under increasing pressure is limited, and at the triple point *c* (1,280 atm. and 151° C.) the rhombic form comes to be in stable equilibrium with liquid. If rhombic sulfur, in open air, is heated very rapidly through 95.5° C., the monoclinic form may not appear and the metastable triple point *d*, for rhombic sulfur + liquid + vapour, may be reached. The two forms have the same vapour pressure only at the transition point, where they are in equilibrium. Above this temperature rhombic sulfur, metastable relative to monoclinic, is higher in vapour pressure and therefore in free energy and chemical activity.

When heated, monoclinic sulfur begins to melt only at a temperature (119° C.) higher than that of point *b*. The initial melting point gradually falls, during melting, toward the final equilibrium value of 114.5° C. as the liquid, consisting internally of two or more interchangeable forms in dynamic allotropy, approaches equilibrium proportions of these forms. The slowness of the approach to equilibrium gives the element a pseudobinary character in its liquid-solid transitions.

The enantiotropic polymorphism of silica involves a number of successive crystalline forms: α-quartz to 573°, β-quartz to 867°, β_2-tridymite to 1,470° and β-cristobalite to 1,723° C., the melting point; in addition, α- and β_1-tridymite and α-cristobalite appear as metastable forms at lower temperatures. Transformations between these phases are sluggish; the liquid, moreover, is easily supercooled to the noncrystalline vitreous condition (silica glass). This tendency to form glass persists in mixtures of silica with various metal oxides.

In monotropy, as contrasted to enantiotropy, one (or more) of the crystalline varieties is always unstable with respect to some stable form. Thus white (or yellow) phosphorus, regularly formed from the vapour of the element, is monotropic with respect to the red (or violet) modification. The vapour pressure of white phosphorus, either as solid or as liquid, is higher at any temperature than that of red phosphorus, and the white form eventually changes, at a rate depending on conditions, entirely to the red. Many organic compounds exhibit monotropy; menthol has four forms, three of them monotropic with respect to the highest melting one.

Some complex organic compounds exhibit stepwise transitions between crystalline and liquid (isotropic) states. The intervening phases, known as liquid crystals or mesomorphic states, may show either enantiotropic or monotropic relations, or both, and their transitions may be represented on the usual phase diagram. The phenomenon was first discovered for cholesteryl benzoate (1888).

Two-Component Systems.—The phase equilibria of a binary system require three dimensions for complete representation, with composition, either weight percentage or mole fraction, plotted perpendicularly to the axes of pressure and temperature. Such complete, three-dimensional phase diagrams are not considered here. Usually, only limited aspects of the phase equilibria are studied for most systems; hence the observations usually may be represented on a plane diagram showing only two of the three variables. Equilibria involving condensed phases—solids and liquids—are investigated principally as temperature-composition relations, either at constant pressure (isobaric) or with the pressure effect ignored when it is relatively small. Relations of pressure and composition and of pressure and temperature, on the other hand, are important for equilibria involving vapour.

Consider first the liquid-vapour relations for a binary solution varying continuously in composition from pure A to pure B, the two liquid components. If the vapour pressure falls continuously from P_A, that of component A, to P_B, that of component B, the isothermal pressure-composition diagram would be, schematically, fig. 4. The diagram consists of three fields, defined by curves representing compositions of coexisting liquid and vapour. These curves, called liquidus and vaporus respectively, meet at the compositions of the pure components. For compositions and pressures above the liquidus the system is entirely liquid, below the vaporus it is entirely vapour. Between the curves liquid and vapour coexist. Thus liquid *l* is in equilibrium with vapour *v*, and its vapour pressure at the temperature of the diagram is P_l.

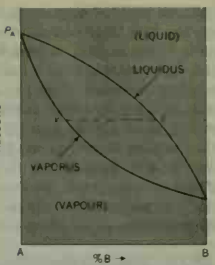

FIG. 4.—EQUILIBRIUM OF BINARY LIQUID AND VAPOUR AT CONSTANT TEMPERATURE

The temperature-composition relations of binary liquid and vapour at constant pressure constitute a boiling point diagram. The system of fig. 4 corresponds to the diagram of fig. 5(a) with the boiling points of all mixtures falling between those of the components. Positions of liquidus and vaporus are now reversed. Liquid of composition *x* begins to boil at T_x, giving off vapour of composition *y*. If this vapour, rich in A, is continually removed, as in open air boiling or in distillation, the residual liquid becomes richer in B and the boiling point rises, along the liquidus curve, toward that of pure B as a limit. Thus the mixture may be fractionated by distillation; the more volatile, lower-boiling component A accumulates in the vapour and hence in the condensate, while B accumulates in the residual liquid phase.

Fig. 5(b) and 5(c) represent systems with a binary maximum (or minimum) in boiling point. (These systems would show a minimum or maximum, respectively, in their isothermal vapour pressure curves.) Separation by fractional distillation in these cases cannot be carried beyond the maximum or the minimum. Liquids on the left of the maximum in fig. 5(b) give a vapour richer in A, and pure A may ultimately be obtained from vapour fractions but the residue cannot pass the composition of the maximum. The same residue composition is reached by the boiling of liquids on the right of the maximum. The liquid at the maximum boils without further fractionation, and without further change in boiling point, to a vapour of the same composition. This constant-boiling liquid, like that at the minimum of fig. 5(c), is called azeotropic, and the system is said to exhibit maximum (or minimum) azeotropy.

Examples for fig. 5(a), 5(b) and 5(c) respectively are the systems acetone-water, water-sulfuric acid, and alcohol-water.

If the components are completely miscible in the solid state, so that the binary system forms a continuous solid solution upon freezing, the relations between solid and liquid phases in freezing or melting may be schematically represented by the curves of fig. 5. The two-phase region of fig. 5(a) would now represent the equilibrium between a liquid solution (higher-temperature phase) as at point *y*, and a solid solution (lower-temperature phase) as at point *x*, with the freezing point falling continuously from that

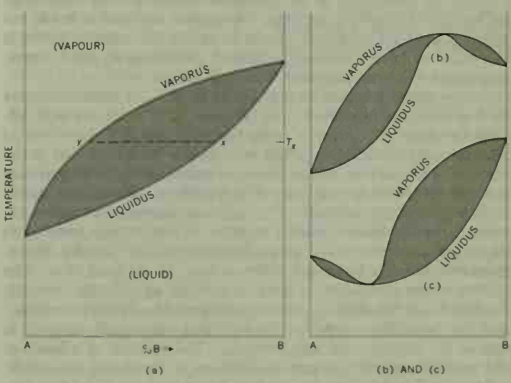

FIG. 5.—BINARY LIQUID-VAPOUR RELATIONS AT CONSTANT PRESSURE (BOILING POINT DIAGRAMS)

of pure B to that of pure A. When any binary liquid is cooled, then, the first trace of solid to form would be richer in B than the liquid, which is in turn enriched in A. If complete equilibrium could be maintained, with sufficiently slow cooling permitting the necessary diffusion through the solid, the phase compositions should continually adjust themselves, and upon complete solidification the solid should consist of a single phase that is uniform throughout in structure and in composition. Since this condition is hardly ever attained, each part of the final solid possesses a varying structure and composition, with the core being richer in B and the surface layer richer in A than the original liquid. The final properties of an alloy, for example, thus come to depend not only on total composition but also on conditions of preparation.

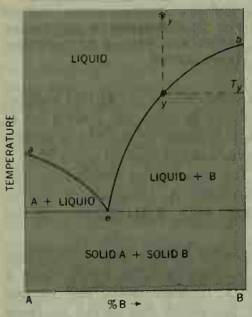

FIG. 6.—PHASE DIAGRAM OF BINARY SYSTEM WITH PURE COMPONENTS AS SOLID PHASES

Continuous solid solution as represented by the curves of fig. 5 is restricted, with few exceptions, to pairs of components isomorphous in the crystalline state and not differing greatly in lattice dimensions. Many examples are known both with continuous fall or continuous rise in freezing point, and with a minimum melting point, as in fig. 5(c). A maximum as in fig. 5(b) is rare.

If the freezing of the binary liquid produces the separate components as pure solid phases, the phase diagram is of the type shown in fig. 6. It consists of two intersecting branches, each falling from the freezing point of a component; curve *ae* represents liquid solution in equilibrium with solid A and curve *be* liquid in equilibrium with solid B. Curve *be* shows the lowering of the melting point of B by component A; it also represents the variation with temperature of the solubility of B in the binary liquid. Solid B begins to precipitate from liquid *y* when the liquid is cooled to temperature T_y, at which point the liquid has become saturated with B. At this temperature, solid B may be dissolved in pure liquid A until its concentration reaches the value *y*, where the liquid is saturated, and further addition leaves solid B in excess. The variation of the mole fraction of B, or (x_B), with the absolute temperature (T) on the curve *be* is given by the equation

$$\frac{dx_B}{dT} = \frac{x_B \Delta H_B}{RT^2}$$

in which R is the gas constant and ΔH_B the heat of solution of B. Near the melting point of pure B, the quantity ΔH_B is the heat of fusion of the solid, and when this is known the equation permits the estimation of the purity of a sample from the change in temperature during melting. A similar expression holds for component A on curve *ae*. Point *e*, called the eutectic point, is the liquid of lowest freezing point and, pertaining to both curves, represents solution saturated with both solids.

As the liquid *y* begins to precipitate B at T_y, it becomes richer in A and its freezing point falls further. The residual liquid follows the curve *be* toward *e* while the quantity of B deposited as primary crystallization product continually increases. At *e* the residual solution freezes at a constant temperature to an intimate mixture of pure A and pure B crystals in proportions corresponding to point *e* itself. This eutectic mixture (so called because it is the lowest-melting mixture of the binary system) is deposited as a secondary crystallization product usually distinguishable visually from the primary pure B (or pure A). The system water-potassium nitrate illustrates fig. 6; the eutectic ($-2.8°$ C., 10.9% KNO_3) is now the intersection of the "ice curve" and the "solubility curve" of the salt, and the eutectic mixture is one of ice crystals and salt crystals. The number of phases at the eutectic, including vapour in addition to liquid and two solids, is four, so that this is an invariant point of the binary system, corresponding to the triple point of a one-component system.

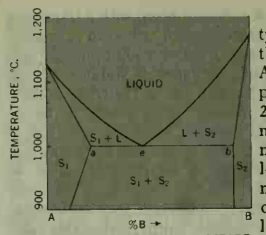

FIG. 7.—SYSTEM LEAD TUNGSTATE (= A)-LEAD SULFATE (= B). S_1 = SOLID SOLUTION OF B IN A: S_2 = SOLID SOLUTION OF A IN B: L = LIQUID

Binary systems of the eutectic type are often useful because of the low melting points obtainable. Although pure cadmium and pure bismuth melt at 321° and 271° C. respectively, suitable mixtures can be used as molten metal baths at temperatures as low as 144° C. Ice may be melted by addition of a salt because of the tendency to form the low-melting eutectic of the system. In some cases the ice-salt mixture may be used to produce low temperature, or as a freezing mixture, because of the endothermic nature of the simultaneous melting (or dissolving) of the solids to form the low-melting liquid. It is thus possible to reach temperatures as low as $-21.3°$ C. from snow and sodium chloride and $-54.9°$ C. from snow and calcium chloride hexahydrate.

If the components dissolve in each other in the solid state to a limited extent, there are still two separate solid phases in the system, a solid ranging in composition from pure A to a limiting concentration of B and one ranging from pure B to a limiting concentration of A. With two solids, the freezing point diagram again consists of two intersecting branches, with the intersection either at a minimum (eutectic type) or at an intermediate temperature (peritectic type). The system lead tungstate-lead sulfate (fig. 7) is of the eutectic type; points *a* and *b* are the limiting solid solutions at the eutectic, which is like that in fig. 6 except that the two solids (*a*, *b*) are not pure components. Fig. 8 shows the peritectic type in the system platinum-silver (Pt-Ag). Curve *ap* represents liquid saturated with platinum-rich solid solution on curve *ac*, and curve *pb* represents liquid saturated with silver-rich solid solution on curve *db*; liquid *p* is in equilibrium with two limiting solid solutions, *c* and *d*.

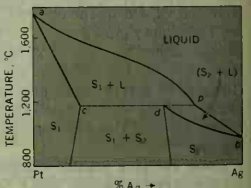

FIG. 8.—SYSTEM PLATINUM-SILVER. S_1 = SOLID SOLUTION OF AG IN PT: S_2 = SOLID SOLUTION OF PT IN AG: L = LIQUID

The limited mutual solubility (or miscibility) of liquids is usually more easily studied than that of solids. While some pairs of liquids, *i.e.*, as alcohol and water, dissolve in each other in all proportions so that they always give a single liquid phase, other pairs form two liquid layers that differ in composition. Unless the mutual solubility is zero, as is practically the case for mercury and water, neither layer is pure. Thus small amounts of ether dissolve in water, but the continued addition of ether leads to formation of a second, lighter layer that at equilibrium is itself a dilute solution of water in ether. Raising the temperature usually increases mutual solubility. The two coexisting layers, or conjugate liquids, then approach each other in concentration, and a temperature may be reached when the two layers become identical and merge with each other, with disappearance of the interface. The system phenol-water has such a consolute point of upper critical solution temperature at 66° C. In the system nicotine-water, the existence of two liquid layers is

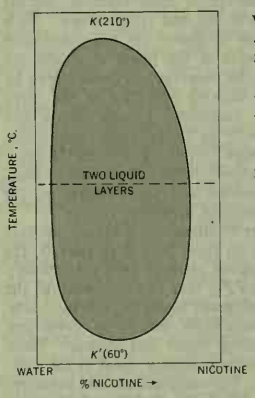

FIG. 9.—SYSTEM WATER-NICOTINE

limited both by an upper and by a lower consolute point (K and K' of fig. 9). Between these temperatures, mixtures having compositions falling within the closed curve separate into two layers, the compositions of conjugate layers being given by points on the curve joined by an isothermal line (horizontal on fig. 9). A mixture having a composition outside the closed curve exists as a single liquid solution. A lower consolute point is relatively rare, and the cooling of the conjugate liquids usually leads eventually to precipitation of one of the solids of the system. Thus the two phenol-water liquid layers come to be in equilibrium with a solid hemihydrate of phenol at 1.7° C.; with vapour present this constitutes a four-phase invariant point of the system.

If the two liquids remain partially miscible up to the boiling point, the boiling point curve of the system, unlike those in fig. 5, consists of two branches. Their intersection then represents the boiling point of the conjugate liquids, which may be either the maximum boiling point of the binary system or some temperature intermediate between those of the components.

The binary liquid, in certain concentration ranges, may produce on freezing a solid compound of the components. Two typical relations for such a system are shown in fig. 10, in which the compound (C) is assumed to have the composition 1A:1B. With three solid phases (A, C and B), the phase diagram consists of three curves, the middle one representing solutions in equilibrium with the solid compound and hence yielding the compound upon freezing. In fig. 10(a) this curve has a temperature maximum at the composition of the compound, and solid C is obtained on cooling solutions of compositions on either side of that of the compound itself, namely from e_1 to e_2. The (generally rounded) maximum of the curve is the melting point of the compound, which is said here to melt congruently to a liquid of its own composition. The two halves of the diagram are like simple eutectic systems (fig. 6) side by side, with eutectic e_1 for solids A and C, and e_2 for C and B. In fig. 10(b), on the other hand, only liquids with composition between p and e (containing excess of B relative to the compound C) give as first crystallization product solid C. The compound in this case decomposes, or melts incongruently, when heated to the temperature T_p (a peritectic point), yielding solid A and liquid p. Although the congruently melting compound on fig. 10(a) is stable as a solid phase up to its melting point (T_c), such compounds in general decompose to some extent in the liquid state, and the greater the extent of dissociation in the melt the flatter is the freezing point curve through the maximum.

The system calcium-magnesium (Ca-Mg) illustrates fig. 10-(a), with the intermetallic compound $CaMg_2$ melting congruently at 718° C. Fig. 10(b) is illustrated by the system aluminum oxide (Al_2O_3 = A) – silica (SiO_2 = B), with the compound $3Al_2O_3 \cdot 2SiO_2$ (= C) melting incongruently at 1,810° C. If the two components form a number of congruently melting compounds varying stepwise in composition between A and B, the phase diagram consists of a succession of curves, each with a maximum marking the melting point and the composition of a compound.

A system may involve both types of compounds and its

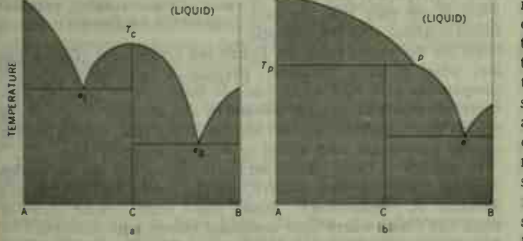

FIG. 10.—FREEZING POINT DIAGRAMS INVOLVING BINARY COMPOUNDS. (a) COMPOUND (C) WITH CONGRUENT MELTING POINT (T_c). (b) COMPOUND (C) WITH INCONGRUENT MELTING POINT (T_p)

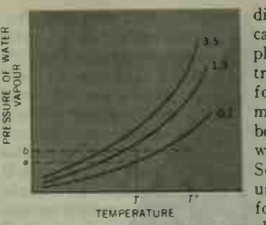

FIG. 11.—DISSOCIATION PRESSURES FOR HYDRATES OF CUPRIC SULFATE, $CuSO_4$ (NOT TO SCALE)

diagram may be further complicated sometimes by polymorphism of these solids. Sulfur trioxide (SO_3) and water (H_2O) form six or seven congruently melting compounds (sulfuric acid being one of them) and several with incongruent melting points. Sodium fluoride (NaF) and uranium tetrafluoride (UF_4) form two compounds of each class besides two that decompose with rising temperature before attaining equilibrium with liquid. In many binary alloys, intermediate solids appear that may be both solid solutions and intermetallic compounds. The first solid solution, or alpha phase, of the system Cu-Zn, extending from pure copper to almost 40% zinc, includes the composition of ordinary brass (30%–33% Zn).

When a binary compound is formed directly and reversibly from a solid and a vapour, as in the reaction of copper sulfate ($CuSO_4$) with water vapour to form the hydrate $CuSO_4 \cdot H_2O$, the vapour pressure of the three-phase univariant equilibrium varies with the temperature. In fig. 11 are plots of pressure against temperature for the following reactions, each for two solids and vapour:

Curve 0,1: $CuSO_4 + H_2O \rightleftarrows CuSO_4 \cdot H_2O$
Curve 1,3: $CuSO_4 \cdot H_2O + 2H_2O \rightleftarrows CuSO_4 \cdot 3H_2O$
Curve 3,5: $CuSO_4 \cdot 3H_2O + 2H_2O \rightleftarrows CuSO_4 \cdot 5H_2O$

At temperature T' the solids $CuSO_4$ and $CuSO_4 \cdot H_2O$ can coexist at equilibrium only under a partial pressure of water vapour, P_{H_2O}, equal to a. If, at this temperature, P_{H_2O} is maintained below a the hydrate dissociates. If P_{H_2O} is raised to the value b all the salt becomes hydrated, but if the monohydrate is now heated to T'' it decomposes. If a sufficient quantity of the anhydrous salt is present the final partial pressure of water in a closed space at T' cannot exceed the equilibrium value a. Thus, for example, magnesium perchlorate, forming a hydrate of extremely low dissociation pressure, is a powerful drying agent for moist gases.

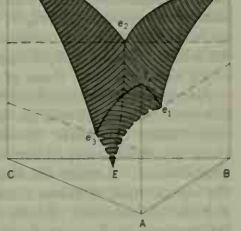

FIG. 12.—FREEZING POINT RELATIONS FOR A TERNARY SYSTEM WITH PURE COMPONENTS AS SOLID PHASES

Three-Component and Multicomponent Systems of Higher Orders.—The phase equilibria of a ternary system (*i.e.*, a system of three components) involve four independent variables, *i.e.*, the independent percentages of two of the components in addition to pressure and temperature. A three-dimensional diagram can represent only three independent variables, and for freezing, or solubility, equilibria of condensed phases the usual relations studied are those of composition and temperature. With composition plotted on an equilateral triangle as the base, and temperature as the vertical axis, the diagram takes the form of a triangular prism, in which pressure is either constant or is assumed to have negligible effect. Fig. 12 shows the type of relation resulting if the components form a single continuous liquid phase and if the only solids appearing on freezing are the separate, pure components (A, B, C). Each of the three surfaces (each of which may be regarded as either a freezing point surface or a solubility surface) gives the temperature at which liquids with compositions falling on that surface first yield a particular solid on cooling: solid C for the surface T_c-e_2-E-e_3, for example. This surface therefore represents ternary liquid solutions in equilibrium with solid C. Points e_1, e_2, e_3 are the eutectics of the separate binary systems. Each represents the temperature and composition of a

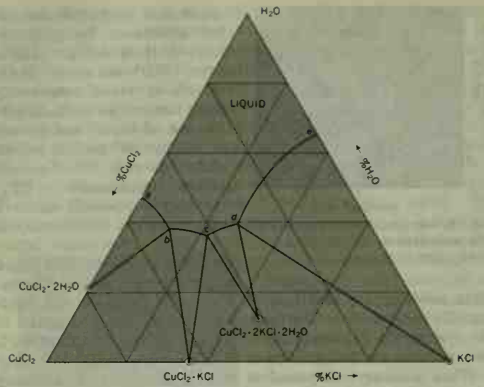

FIG. 13.—PHASE DIAGRAM OF SYSTEM $CuCl_2$-KCL-H_2O AT 75° C. PERCENTAGE OF EACH COMPONENT IS MEASURED FROM OPPOSITE SIDE

binary liquid in equilibrium with two solids (*cf.*, fig. 6). Point *E*, the liquid of lowest freezing point and in equilibrium with all three solids, is the ternary eutectic. When only pure (or almost pure) components appear as solids from a multicomponent solution each additional component causes a further decrease in the minimum (eutectic) melting point. The eutectic of the ternary alloy bismuth-cadmium-tin is at 102.5° C., and the quaternary eutectic, with lead added, is at 70° C.

A horizontal, isothermal section of fig. 12 represents the phase equilibria, specifically solubility relations, of the ternary system at a given temperature. Fig. 13 is the solubility diagram for the system copper chloride-potassium chloride-water ($CuCl_2$-KCl-H_2O) at 75° C. Compositions in the region labeled "Liquid" represent unsaturated solutions. The four curves from *a* to *e*, delimiting this region, represent, successively, the solubility, in ternary solutions, of each of the four solid phases of the system at this temperature: curve *ab* represents compositions of solutions saturated with $CuCl_2 \cdot 2H_2O$; *bc* with the double salt $CuCl_2 \cdot KCl$; *cd* with the hydrated double salt $CuCl_2 \cdot 2KCl \cdot 2H_2O$; and *de* with KCl. Points *b*, *c*, *d*, denote compositions of solutions saturated with two salts, those of the adjacent curves.

A system of four components, such as an alloy of four metals or the system of water and the salts sodium chloride, sodium sulfate and sodium carbonate, involves five independent variables, for there are three independent concentrations besides pressure and temperature. A three-dimensional figure is required to represent the composition relations alone at fixed pressure and temperature. For the aqueous salt system, for example, this figure would be a tetrahedron with water as an apex, and each side touching this apex would be the solubility isotherm, like fig. 13, of a ternary system of water and two salts. Surfaces and curves within the tetrahedron would then represent the simultaneous solubility relations in the quaternary solutions containing all three salts.

Difficulties both of experimentation and of graphical representation mount with each additional component. Nevertheless, at least partial studies of some high-order multicomponent systems have been made. Perhaps the most notable example is the work of J. H. van't Hoff on the complex system of sea water, treated essentially as a six-component system of the chlorides and sulfates of sodium, potassium, magnesium and calcium in water. Significant aspects of the phase equilibria were established at a number of temperatures. This work was of practical importance in connection with the utilization of the Stassfurt (*q.v.*) salt deposits and of theoretical interest as a basis for the interpretation of the geological history of their formation.

PHEASANT, any of about 50 species of game birds of the Old World, belonging to the family Phasianidae (which also includes the new and old world quail and partridges). The males are brightly coloured, generally with long tails; the females are inconspicuously coloured. A few, like the tragopans (*Tragopan*) and impeyans or monals (*Lophophorus*) are short tailed; they are intermediate between the pheasants and the partridges.

The typical pheasant (*Phasianus colchicus*) was according to legend introduced into Europe by the Argonauts from the banks of the Phasis in Asia Minor and was later supposedly brought to England by the Romans. As a wild species it occurs in many parts of Eurasia in a number of local races, of which the Japanese green pheasant is especially distinct. The Chinese ring-necked variety was introduced into Oregon in 1881 and others were brought to the eastern United States from England. Pheasants now occur across the northern United States and southern Canada, where in many places they are the most important game bird. They are also raised for sport in shooting preserves in the United States and Britain (*see* GAME BIRDS). Pheasants nest in late April and early May, lay 7 to 18 olive-buff eggs in a nest on the ground hidden by a tussock of grass or a small bush. The male has brilliant plumage and red wattles; the female is protectively coloured in mottled brown. The wings are short, the tail long. In the breeding season sets of erectile feathers on each side of the head give the cock a horned appearance. The birds are polygamous, the male maintaining a harem. They feed on grain, seeds, shoots and insects. Both sexes fly and run well.

PETE CZURA

MALE RING-NECKED PHEASANT (PHASIANUS COLCHICUS)

The ornaments of pheasants are strikingly displayed in courtship, the peacock (*q.v.*) being the most notable example (*see* COURTSHIP, ANIMAL). The splendid Argus pheasant (*Argusianus*) and the ocellated pheasant (*Reinardia*) are related to the peacock. The rare Congo peacock (*Afropavo*), discovered in 1926, is the only true pheasant found in Africa. All the domestic fowls are descended from the Indian red jungle fowl (*Gallus gallus*), which is also a pheasant. Because of their beauty and the comparative ease with which some of them can be raised in captivity, pheasants are in great demand by aviculturists. Some of the species live in such dense cover and are so shy that, were it not for captive individuals, man would never set eyes upon them.

In addition to those mentioned above, favourites are the golden pheasant (*Chrysolophus pictus*) and the lovely Lady Amherst's pheasant (*C. amherstiae*). Many come from remote areas of India and China where their continued existence is threatened by destruction of the habitat and by hunters who snare them for food.

See W. Beebe, *Monograph of the Pheasants* (1918–22); J. Delacour, *Pheasants of the World* (1951).
(DN. A.)

PHEIDIAS: *see* PHIDIAS.

PHEIDON (probably 7th century B.C.), a powerful king of early Argos, in Greece. The Dorians of Argos considered that they inherited the traditional supremacy of Mycenae, Agamemnon's capital, and in the legend of the Dorian division of the Peloponnese most of the northeastern cities (Sicyon, Phlius, Epidaurus and others, but not Corinth) were reckoned to belong to the "lot" of Temenus, the Argive founder. A tradition of uncertain value asserts that Temenus' successors were weak kings till Pheidon, the tenth, who reunited the "lot of Temenus": Herodotus attests that he seized Olympia and held the festival himself, and that he established the standard system of measures in the Peloponnese.

Herodotus, naming Pheidon's son Leocedes among the suitors of Agariste, daughter of Cleisthenes of Sicyon, dates Pheidon by implication *c.* 600 B.C., but at this time the tyrannies of Corinth and Sicyon were at the height of their power and there is no room for a period of Argive ascendancy. Some later writers assigned him to the 8th century, but there are also grounds for doubting this. The evidence on his seizure of Olympia is confused, Pausanias dating it to 748 while others say that the Eleans held the presidency without a break till 672 or 668. There are still advocates of the 8th-century date, but most modern writers prefer the early 7th century. We may then attribute to him the defeat of Sparta at Hysiae, on the pass leading up from the southern Argolid into Arcadia, which Pausanias dates to 669.

The most striking evidence of his power is his ability to march across the Peloponnese and seize Olympia. A system of measures called Pheidonian certainly existed later in the Peloponnese and its colonies, and also in Athens before Solon, but Ephorus' statement that Pheidon was the first to coin silver money must rest on a misunderstanding: the beginning of coinage in mainland Greece is now dated too late in the 7th century for Pheidon. Aristotle says that he exceeded the traditional bounds of kingship and became tyrant; since he was legitimately king, the meaning must be that he asserted the royal power more effectively than was usual in this aristocratic period. The Argive recovery did not last long against the combination of Sparta and Elis, and the northeastern cities were soon independent under their own tyrants.

See P. N. Ure, *The Origin of Tyranny*, ch. vi (1922); A. Andrewes, *The Greek Tyrants*, ch. iii (1956). (A. As.)

PHELPS, WILLIAM LYON (1865–1943), U.S. teacher and author, did much to popularize the teaching of contemporary literature. Born on Jan. 2, 1865, in New Haven, Conn., he attended Yale University (B.A. 1887, M.A. 1891) and Harvard University (Ph.D., 1891). He taught at Harvard for a year, and then returned to Yale where he was for 41 years a member of the English department and Lampson professor from 1901 until his retirement in 1933. For years his students voted him Yale's most inspiring professor and thronged to his classes on contemporary drama, in the teaching of which he was a pioneer, and on Tennyson and Browning. In 1895 he taught the first U.S. college course in the modern novel, doing much to introduce Russian novelists to U.S. readers. A popular lecturer and critic, his literary essays in *Scribner's Magazine* and other periodicals and his syndicated newspaper column, "A Daily Thought," brought him an audience estimated in the millions.

As a critic he helped make the popular reputation of Thornton Wilder. An object of the scorn of H. L. Mencken, he endorsed Mencken's *Prejudices*. He died on Aug. 21, 1943, in New Haven.

His numerous books were devoted chiefly to English literature. His *Autobiography with Letters* was published in 1939.

See also F. H. Barber's *Fellow of Infinite Jest* (1949).

PHÉLYPEAUX, the family whose long tenure of offices of state in France made it one of the so-called ministerial dynasties of the 17th–18th centuries.

PAUL PHÉLYPEAUX, SIEUR DE PONTCHARTRAIN (1569–1621), the son of a councilor in the presidial court at Blois, began a career in the king's service in 1583 and was appointed one of the four secretaries of state in April 1610. He died at Castelsarrasin, in Languedoc, in October 1621, during the campaign against the Huguenots. His memoirs (published 1720) deal with the affairs of the regency of his patroness, Marie de Médicis.

As Paul's son LOUIS I, SIEUR DE PONTCHARTRAIN (1613–85; *see* below) was an infant in 1621, the secretaryship of state was taken over by Paul's elder brother, RAYMOND, SIEUR D'HERBAULT (1560–1629), who in 1626 became the first secretary of state to be assigned the sole administration of all foreign affairs and who also had the department of Huguenot affairs, as well as control of a number of provinces. Herbault's son LOUIS I, SIEUR DE LA VRILLIÈRE (1598–1681), secured the secretaryship in 1629, with the Huguenot department and more provinces, but without foreign affairs. La Vrillière was succeeded by his son BALTHAZAR, MARQUIS DE CHÂTEAUNEUF (*c.* 1638–1700), during whose lifetime the Huguenot department lost much of its scope because of the revocation of the Edict of Nantes (1685). Châteauneuf's son LOUIS II, MARQUIS DE LA VRILLIÈRE (1672–1725), who obtained the Huguenot department in 1700, was the only secretary of state to be retained in effective function during the system of councils (1715–18) under the regency of the duc d'Orléans, when he was moreover secretary general of the council of regency. He secured the reversion of his old secretaryship, with the Huguenot department, for his son LOUIS, COMTE DE SAINT-FLORENTIN (1705–77), in 1723. Saint-Florentin, completely obsequious to King Louis XV, further obtained the department of the king's household (with the affairs of the clergy) in 1749, the rank of minister of state in 1751, the title of duc de La Vrillière in 1770, and temporary management of foreign affairs in 1770–71. Hated for his ruthlessness toward *parlements*, heretics, and freethinkers, he was at last dismissed by Louis XVI in 1775.

Louis I de Pontchartrain (*see* above) became president of the Chambre des Comptes in Paris in 1650; but by refusing his assent to the condemnation of Nicolas Fouquet (*q.v.*) in the 1660s, he forfeited all hope of compensation for his father's secretaryship of state. His son LOUIS II, COMTE DE PONTCHARTRAIN (1643–1727), who was quite unexpectedly appointed premier president of the Breton Parlement in 1677, restored the Pontchartrain fortunes, becoming intendant of the French finances (1687–89), controller general of the finances (1689–99), minister of state (1690–1714), secretary of state with the marine department and the king's household (1690–99), and finally chancellor of France (1699–1714). His son JÉRÔME, COMTE DE PONTCHARTRAIN (1674–1747), was designated for the secretaryship in 1693 and took the departments over in 1699. Tactless and incompetent, he was forced to resign his office to his young son JEAN FRÉDÉRIC, COMTE DE MAUREPAS (*q.v.*) in 1715.

PHENACETIN, a drug also called acetophenetidin, is an effective analgesic and antipyretic for headaches, colds, muscular pains, and rheumatic conditions. It is one of the three ingredients used in APC tablets, the others being aspirin and caffeine.

Phenacetin crystallizes from water in colourless plates that melt at 135° C. It is soluble in about 70 parts of hot water and in about 1,400 parts of cold water. It is prepared by acetylating paraphenetidine or by heating paraacetylaminophenol and potassium ethyl sulfate with alcoholic soda to 150° C. Paraphenetidine is prepared by treating the sodium salt of paranitrophenol with ethyl iodide and reducing the nitrophenetole to paraphenetidine or aminophenetole. The yield may be doubled by diazotizing paraphenetidine, coupling with phenol, ethylating, and reducing.

The formula for phenacetin is $C_{10}H_{13}NO_2$ and its chemical name is paraethyoxyacetanilide.

PHENACITE, a rare mineral consisting of beryllium orthosilicate, occasionally used as a gem stone. In general appearance it is not unlike quartz, for which indeed it had been mistaken, and was for this reason named from the Greek meaning a deceiver.

For gem purposes the stone is cut in the brilliant form but it is not in general use; fine examples are seldom seen outside of private or museum gem collections. The indices of refraction are higher than those of quartz, beryl, or topaz; a faceted phenacite is consequently rather brilliant and may sometimes be mistaken for diamond.

Phenacite has long been known from the emerald and chrysoberyl mine on the Takovaya stream, near Sverdlovsk in the Urals, where large crystals occur in mica schist. It is also found with topaz and microline in the granite of the Ilmen mountains in the

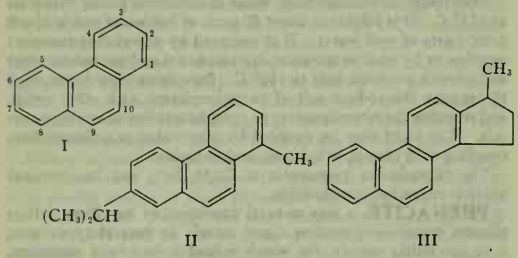
southern Urals and of the Pikes Peak region in Colorado. Large crystals of prismatic habit have been found in a feldspar quarry at Kragero, Nor., and clear lenticular crystals are abundant at San Miguel de Piricicaba in Minas Gerais, Braz.

The formula of phenacite is Be_2SiO_4. It occurs as isolated crystals, which are rhombohedral with parallel-faced hemihedrism and are either lenticular or prismatic in habit. There is no cleavage, the fracture is conchoidal, and the crystals are sometimes perfectly colourless and transparent, but more often grayish or yellowish and only translucent. The hardness is high, being 7.5–8; the specific gravity is 2.98. (Cl. F.)

PHENACODUS, a genus of hoofed mammals, now extinct, of the family Phenacodontidae (order Condylarthra). The two best-known species are represented by complete skeletons found in the Bighorn Basin of Wyoming in 1881. *Phenacodus*, appearing in the Early Eocene of Europe and North America, attained the size of a pig or a fox. The teeth were short crowned, with low rounded cusps, the dentition unreduced, the premolars smaller than the molars and of simple pattern. The feet were five toed but the first and fifth digits were considerably reduced; the small flattened hoofs resembled those of the tapir. The arrangement of the wrist-bones was serial, the upper row directly overlying the lower ones, as in the hyrax and the elephant, instead of alternating as in other hoofed animals. The anklebone in the hind foot had a distinct neck and convex rounded head like that of carnivores. This character distinguishes the Condylarthra from the higher ungulates, as the primitive construction of their teeth distinguishes them from the variously specialized ungulate tooth patterns. The brain was small and of inferior structure. (W. D. M.)

PHENANTHRENE, an aromatic hydrocarbon of little importance in itself but of great value and interest because its structural skeleton occurs as a part of many natural products, including the steroids. Phenanthrene was discovered in 1872 by Rudolf Fittig and Eugen Ostermayer. It has the same composition ($C_{14}H_{10}$) as anthracene and is found with it in coal tar distillates boiling between 300° and 400° C. Phenanthrene crystallizes as colourless leaflets; its melting point is 101° C and its boiling point is 332° C. The commercial product is contaminated with anthracene, fluorene, carbazole, and other substances. It may be purified by treatment with maleic anhydride to remove anthracene, followed by azeotropic distillation with ethylene glycol to remove fluorene, and then treatment with sodium to remove traces of sulfur compounds.

Phenanthrene is oxidized by chromic acid to the 9,10-phenanthrenequinone and diphenic acid (2,2′-biphenyldicarboxylic acid). This and a variety of synthetic methods of preparation establish its structure (I).



Phenanthrene also has been obtained from a Rumanian petroleum distillate, and 1,8-dimethyl- and 1,2,8-trimethylphenanthrene have been isolated from high-boiling fractions of a Kuwait petroleum. The last-named is a major product of dehydrogenation of tetracyclic triterpenoids and of many diterpenoids. Retene (1-methyl-7-isopropylphenanthrene), structure II, is found in fossilized pinewood and in the highest boiling fractions of pinewood tar. It is formed by dehydrogenation of abietic acid.

The completely or partly hydrogenated phenanthrene nucleus is present in opium alkaloids (notably morphine), resin acids, sterols, bile acids, sex hormones, adrenal cortical hormones, heart poisons, saponins, and the steroid alkaloids. The key to the elucidation of the structures of the various groups of steroids was the establishment by synthesis of the structure of Diels's hydrocarbon, formed from members of this group by selenium dehydrogenation, as 3′-methyl-1,2-cyclopentenophenanthrene (structure III).

Phenanthrene forms addition compounds on the 9,10 bond. Hydrogenation gives as the initial product 9,10-dihydrophenanthrene; the unstable 9,10-dichloride and 9,10-dibromide may also be prepared. A large variety of substitution products has been obtained. Nitration for example, gives all five possible mononitro derivatives.

See L. F. and Mary Fieser, *The Chemistry of Natural Products Related to Phenanthrene*, 3rd ed. (1949), *Steroids* (1959). (J. W. Ck.)

PHENIX CITY, a city of eastern Alabama, U.S., in Russell County, on the Chattahoochee River, is opposite Columbus, Ga., of which it is a residential and industrial suburb. Manufactured products include lumber, caskets, and embalming supplies.

In 1923 the legislature extended the corporate limits of Phenix City to include the town of Girard but it did not alter the county boundaries. In 1927, a branch courthouse was established, in that part of Phenix City which had formerly been Girard, to maintain jurisdiction over the northern division of Russell County. The county boundaries were finally altered in 1932, to include all of Phenix City in Russell. The legislature in 1943 provided for the transfer of all records from the old county seat, at Seale, to Phenix City. For comparative population figures *see* table in ALABAMA: *Population.* (P. A. B.)

PHENOLOGY, literally the study of phenomena or happenings, is applied to the recording and study of the dates of recurrent natural events (such as the flowering of a plant, or the first or last appearance of a migrant bird) in relation to seasonal climatic changes. Phenology thus combines ecology with meteorology.

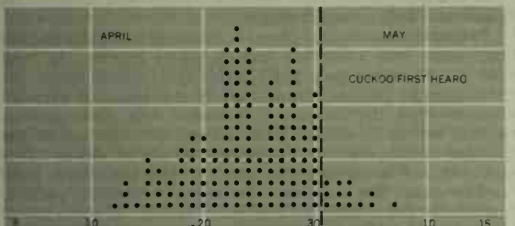
The weather factor that has the greatest influence on recurrent events in temperate climates is almost always temperature; in tropical areas it may be rainfall, humidity, or some other factor. The length of day, which fluctuates throughout the year but is always the same on the same date in every year, often determines the average date of natural events, but not the variation from year to year in a single locality. With resident species these local events are influenced by previous weather conditions in the area; with migrant animals dates of arrival are affected more by conditions at the start of and during their flights. The accompanying figure shows the Marsham records (*see* below) for the first appearance of two migrant birds, the cuckoo and the swallow, in eastern England as examples of the range of date of single annually recurring events over a period of nearly 200 years in the same locality. These data indicate that the swallow generally appears a few days earlier than the cuckoo, and is considerably more variable in its arrival date.

In addition to comparisons of the same event in different years in one locality, phenology is also concerned with studies of the times of the same event in different localities in the same year (when differences of geographic position, soil, slope, shelter, etc., are involved), and of the sequence of different events in one locality during the annual cycle of climate and biological changes. Phenological observations are of importance to farmers and gardeners, and to beekeepers who want to know when nectar-secreting flowers are at their peak production. The best date for spraying for insect pests, particularly of fruit trees in the spring, is determined by the state of development of the leaf and flower buds, which varies from year to year; and the study and application of this is a branch of phenology. In the Netherlands the Ministry of Agriculture informs farmers, a short time in advance, of the best date to start potato harvesting in relation to the state of the crop and the prevalence of certain fungus diseases. Phenological records also have medical applications: they are used to assess the flowering seasons of plants whose pollens cause hay fever.

Although the word "phenology" was first used about 1862, in England the study began as early as 1736, with Robert Marsham's observations of the seasonally recurring events involving plants, insects, and birds in his village in Norfolk, Eng. The Marsham records were continued by Robert's descendants until 1950, except for a break of 25 years. Before 1770 the naturalist Gilbert White

recorded the dates of the first appearances of 20 species of migratory birds at Selbourne, Hampshire, Eng. In 1875 the Royal Meteorological Society of London organized observations of certain plants, birds, and insects, publishing an annual report up to and including 1947. A brief history of phenology in the United Kingdom was given by J. E. Clark in 1936.

In the United States an early phenological study was J. Bigelow's "Facts Serving to Show the Comparative Forwardness of the Spring Season in Different Parts of the U.S.A." (1817; see *Bibliography*). In 1918, A. D. Hopkins, in an article called "Bioclimatic Laws," proposed a method for determining the range of date of occurrence of a seasonal event. His study of agricultural and forest conditions, particularly in the Midwestern U.S., suggested that if the date of a spring event was known at one locality, then the probable date of its occurrence at other localities in the same year would be four days later for each degree of latitude to the north, for each five degrees longitude to the east, and for each 400 ft. rise in altitude. Autumnal events would be approximately the same intervals earlier. Hopkins used his laws (with some empirical corrections) to advise farmers on the best date for certain agricultural operations, in relation to known dates at a particular experimental station. For example, he suggested the best date to sow winter wheat, which, if planted too early, was attacked by fruit fly and if planted too late would suffer from frost. His laws were of value in the comparatively simple weather conditions of the Midwest, where the spring isotherms move northeast at approximately the rates he indicated, but they do not hold for other areas where climatic changes are much more complicated. For example, in the British Isles some spring events happen earlier in the north than in the south. This is due to the unusual climatic conditions, including the influence of the Atlantic Ocean and the Gulf Stream, which result in a mean January temperature in the



PHENOLOGICAL RECORD SHOWING THE FIRST YEARLY APPEARANCES OF THE CUCKOO AND SWALLOW IN EASTERN ENGLAND

north of Scotland and the west of Ireland as high as that in the south of France. In general, spring events in Britain are earlier in the west than in the east.

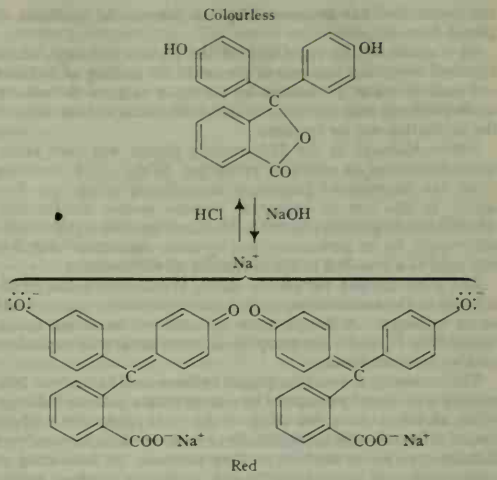
PHENOLPHTHALEIN, an organic chemical compound of the aromatic series that has two uses: (1) as an indicator for acids and bases in volumetric analysis; (2) as a cathartic drug. The phthaleins are prepared by condensing phenols (*q.v.*), with



phthalic anhydride (*q.v.*), phenol itself giving rise to phenolphthalein together with a small quantity of fluorane.

Phenolphthalein is obtained when phenol and phthalic anhydride are heated with concentrated sulfuric acid. It precipitates as colourless crystals (mp 250°–253° C) and is nearly insoluble in water, but the crystals dissolve in dilute alkaline solutions (pH 8.3 or higher) with the appearance of a red-violet colour that is due to the formation of the red disodium salt. If an excess of alkali is added, the solution becomes colourless as the colourless trisodium salt is formed. Crystals may be reprecipitated from these solutions by the addition of an acid. The use of phenolphthalein as an indicator is based on this remarkable colour change. (*See* also INDICATOR, CHEMICAL.)

Phenolphthalein is used extensively as a cathartic under many proprietary drug names. It dissolves in the bile and intestinal fluid, which are slightly alkaline, and, since it irritates the intestine, causes intestinal peristalsis and evacuation. *See* also CATHARTIC.

PHENOLS, a large class of organic substances of which phenol (hydroxybenzene) is the parent compound. They are characterized by the presence of at least one hydroxyl group attached to the benzene ring. Members of the group, in addition to phenol, include the cresols (*q.v.*; or methyl phenols), the xylenols (dimethyl phenols), the dihydroxybenzenes (pyrocatechol, resorcinol [*q.v.*], and hydroquinone), trihydroxybenzene (pyrogallol; *q.v.*), the aminophenols, the halophenols, the nitrophenols (*e.g.*, picric acid; *q.v.*), and the alkylated phenols (*e.g.*, thymol, or 5-methyl-2-isopropyl-1-phenol). Important phenol derivatives include vanillin and anisole.

Phenol, or carbolic acid, was discovered in 1834 by F. F. Runge, who separated it in crude form from coal tar and called it *Karbolsäure*. In 1841 A. Laurent produced the pure substance, again from coal tar, and named it *hydrate de phényle* or *acide phénique*. The term "phenol," which was later used, was introduced by C. F. Gerhardt. He prepared the substance in 1843 by the dry distillation of salicylic acid in the presence of lime. In 1867 A. Wurtz and F. A. Kekulé von Stradonitz discovered the synthesis from benzene, a process still of commercial importance involving the fusion of a strong alkali with the alkali salt of benzenesulfonic acid.

Phenol is found in coal tar, in wood tar, and in many other products derived from the pyrolysis of animal and vegetable matter. In small quantities it is also present in Galician and Caucasian petroleum. It is a product of animal metabolism and, bound to other substances, it occurs in the urine of many mammals.

The commercial manufacture of phenol began in 1860. Originally this substance was obtained solely from coal tar. In the early years of the 20th century, and particularly during World War I, the demand exceeded the supplies available from coal tar,

and production was augmented by the commercial synthesis of phenol from benzene.

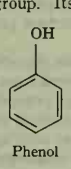
As a result of the rapid rise of the plastics industry, which absorbed increasing amounts of phenol in the making of Bakelite and epoxide resins, production by synthesis outgrew the volume recovered from coal tar, until by mid-20th century about 90% of the production was by synthesis.

Uses.—Although in the 19th century phenol was used extensively because of its antiseptic properties, its use in the operating room was discontinued because of its irritating action (*see* POISON). It also lost its important position among disinfectants, where it was largely supplanted by its homologues of higher molecular weight, by its derivatives, and by other chemicals. But it is still used as a standard in the evaluation of disinfectants.

The great demand for phenol during World War I can be attributed to the extensive use of its trinitro derivative (picric acid) as an explosive. Although made by some of the Allies during World War II, it did not compare in importance with explosives such as trinitrotoluene.

The increasing demand for phenol in the second half of the 20th century was caused principally by the expanding plastics industry, which absorbed about two-thirds of the total production. There phenol is treated with formaldehyde to make the infinite variety of Bakelite-type resins used for molding purposes, for laminating of paper, cloth, and wood, for adhesives, protective coatings, paints, and many other uses. For the epoxide-type resins, phenol is reacted with acetone to form bisphenol A (4,4′-isopropylidenediphenol), which in turn is condensed with epichlorohydrin. Roughly one-fourth of the output went to the chemical and pharmaceutical industries for conversion into such derivatives as salicylates, chlorophenols, alkyl phenols, phenyl phosphates, nitrophenols and phenolsulfonic acids. The production of salicylic acid was one of the best-known outlets for phenol. From it many medicinals (*e.g.,* aspirin), flavours, and dyes were prepared. The chlorophenols are important as bactericides, fungicides, selective herbicides (2,4-dichlorophenoxyacetic acid, or 2,4-D), and starting materials in the production of pharmaceuticals and photographic chemicals. The alkyl phenols are useful as oxidation inhibitors (*e.g.,* di-*tert*-butyl-*meta*-cresol), starting materials for drying-oil-soluble varnish resins (*e.g.,* para-*tert*-butylphenol), and as reagents in the manufacture of synthetic detergents. Triphenyl phosphate is a plasticizer used in cellulose acetate film, and phenolsulfonic acids find application principally in the production of synthetic tanning agents. The remaining production was used as selective solvents in the refining of lubricating oils, the extraction of aromatic fractions (toluene) from petroleum distillates, and for many other purposes. (*See* also ADHESIVES; ANTIOXIDANTS; PLASTICS: *Thermosetting Resins;* RESINS: *Synthetic Resins.*)

Properties.—Phenol is closely related to benzene, differing only in that one of the six hydrogen atoms in the benzene ring is replaced by a hydroxyl (OH) group. Its formula is $C_6H_5{\cdot}OH$. Thus



Phenol

it stands in the same relation to benzene as methyl alcohol, $CH_3{\cdot}OH$, does to methane, CH_4. (*See* also CHEMISTRY: *Hydroxy Compounds.*)

Although it has some properties that resemble those of the aliphatic alcohols, in particular of the tertiary alcohols, phenol cannot be classified as an alcohol. It is characterized by its acidic nature and its readiness to form salts with strong bases. Phenol is the prototype of the hydroxylated members of the benzene series.

Phenol has a molecular weight of 94.11. At atmospheric pressure it boils at 182° C. It solidifies at 41° C into colourless needles. At 25° C its density is 1.072 and its refractive index at 41° C is 1.5425. It has a characteristic pungent odour and in dilute water solution a sweetish taste. In more concentrated form it is poisonous and produces burns on the skin. At room temperature phenol is sparingly soluble in water. If more than 8% by weight of phenol is present, two phases appear in the solution, a bottom layer consisting of phenol with some dissolved water and a top layer of water containing about 8% phenol. As the temperature is elevated, the mutual solubility increases, until above 66° C phenol and water become soluble in all proportions. Phenol is readily soluble in alcohol, ether, chloroform, carbon disulfide, glacial acetic acid and the hydrocarbons of the aromatic series. It is less soluble in the liquid hydrocarbons of the aliphatic series. Because of its acidic nature, it dissolves readily in solutions of alkalies with the formation of alkali-metal salts. These salts are readily decomposed by the addition of acids. Similarly to ordinary alcohols, phenol can be esterified with carboxylic acids, although the reaction does not proceed with the same ease and often requires the action of the chloride or anhydride of the carboxylic acid or an alkali-metal salt of phenol. It can be converted into an ether by treating its sodium or potassium salt with an alkyl halide, such as methyl iodide, or by treating it under elevated temperature and pressure with acetylenes in the presence of alkaline catalysts.

As a typical derivative of benzene, phenol can be sulfonated, nitrated, and halogenated. The presence of the hydroxyl group enhances the reactivity of the benzene ring, so that milder conditions are indicated to control the reactions. Halogenations proceed quantitatively to the trihalide stage, a fact that is useful in the analysis for phenol. Substitutions take place principally in positions ortho and para to the hydroxyl group. Hydrogen, in the presence of active catalysts, will add to phenol to form cyclohexanol or, under more drastic conditions, cyclohexane. Of great commercial importance is the readiness with which phenol reacts with aldehydes, in particular formaldehyde, to form condensation products of high molecular weight.

Preparation.—Natural phenol is recovered at coal tar distillation plants from a distillate fraction boiling between 160° and 230° C. To extract the phenol together with its homologues—the various cresol (methyl phenols) and xylenol (dimethyl phenols) isomers—from this fraction, it is washed with dilute aqueous sodium hydroxide solution. To "spring" the acids out of the aqueous solution the extract is purified and treated with an acidic material, such as carbonic acid, which is often available in stack or kiln gases. The acids thus liberated are withdrawn, purified, and finally fractionally distilled under vacuum to yield phenol in various grades of purity followed by the cresol and xylenol cuts.

Synthetic phenol is produced from benzene mainly by three general procedures which may be classified according to the main process steps as follows:

1. Sulfonation process, which consists in the treatment of benzene with sulfuric acid and subsequent fusion of the resulting benzenesulfonic acid with sodium hydroxide to form sodium phenoxide, which is dissolved in acids to liberate phenol.

2. Chlorination process, which consists in the treatment of benzene with chlorine and subsequent hydrolysis of the resulting chlorobenzene with steam or with aqueous alkaline solutions to form phenol or alkali phenoxide solutions, the latter being treated with acids to liberate phenol.

3. Cumene process, which consists in the reaction of benzene with propylene to form cumene (monoisopropylbenzene); oxidation of the cumene with air to make cumene hydroperoxide; and, finally, cleavage of this hydroperoxide to produce phenol and acetone.

In the sulfonation process benzene is caused to react with an equivalent amount of concentrated sulfuric acid to form monobenzenesulfonic acid according to the equation

$$C_6H_6 + H_2SO_4 \rightarrow C_6H_5SO_3H + H_2O$$

Since the reaction slows down as the reactant sulfuric acid becomes diluted with the water of reaction, the process is often carried out by passing benzene vapour through a sulfuric acid bath, maintained at a temperature above 100° C, in such a way that only a portion of the benzene reacts while the rest escapes as vapour together with the water formed in the reaction. The vapours are condensed, the water is separated, and the benzene is returned to the sulfonation bath. At the end of the cycle there is obtained in

the bath benzenesulfonic acid which is essentially free of sulfuric acid and which can be used directly in the fusion step without the laborious intermediate steps necessary if appreciable quantities of free sulfuric acid remain dissolved in the sulfonation product. The second, so-called fusion, step in the process proceeds according to the reaction

$$C_6H_5{\cdot}SO_3H + 3NaOH \rightarrow C_6H_5{\cdot}ONa + Na_2SO_3 + 2H_2O$$

In practice this operation is carried out in cast-iron vessels. Caustic soda in excess of the theoretical requirement is first charged and heated to about 300° C. Then the benzenesulfonic acid or its sodium salt is pumped into the molten mass. After about six hours the reaction mixture is plunged into aqueous-process liquors in which sodium sulfite crystallizes out because of its low solubility in strongly alkaline solutions. The solution is filtered, and the filtrate, containing sodium phenoxide and residual free caustic soda, is treated with sulfuric acid to liberate the phenol and to convert the soda into sodium sulfate. A final distillation of the phenol removes water and furnishes the marketable product.

In the chlorination process, benzene is treated with chlorine to form monochlorobenzene according to the equation

$$C_6H_6 + Cl_2 \rightarrow C_6H_5{\cdot}Cl + HCl$$

The reaction is carried out in cylindrical vessels. Iron is added to the charge as a catalyst. To repress the formation of the more highly substituted polychlorobenzenes, an excess of benzene is maintained in the reaction zone. The resulting crude chlorination product is treated with a dilute caustic soda solution to free it of by-product hydrogen chloride.

After settling, the product is subjected to fractional distillation to separate from it the nonconverted benzene and to purify the monochlorobenzene. The more highly chlorinated products remain in the still bottoms. The conversion of monochlorobenzene into phenol is commercially accomplished by any one of the following reactions:

(1) $C_6H_5{\cdot}Cl + H_2O \rightarrow C_6H_5{\cdot}OH + HCl$
(2) $C_6H_5{\cdot}Cl + 2NaOH \rightarrow C_6H_5{\cdot}ONa + NaCl + H_2O$
(3) $C_6H_5{\cdot}Cl + Na_2CO_3 + H_2O \rightarrow C_6H_5OH + NaCl + NaHCO_3$

Reaction 1, in the presence of a catalyst, proceeds in the vapour phase at about 500° C and atmospheric pressure. Reaction 2 is carried out in the liquid phase at high pressure and temperature in corrosion-resistant autoclaves. The resulting sodium phenoxide solution is treated with the by-product hydrogen chloride from the chlorination step to liberate the phenol. Reaction 3 is utilized in the Dow Chemical Co. process in which chlorobenzene and soda ash solution are pumped through long copper coils at a pressure of 3,000 lb. per sq.in. and at about 320° C. After the mixture is cooled, the pressure is released and free phenol separates from the bicarbonate solution. Diphenyl ether appears as the product of a side reaction. Fortunately, its formation can be suppressed by returning some of it to the mixture entering the hydrolysis step. For final purification the phenol is subjected to a fractional distillation under vacuum.

Since the vapour-phase hydrolysis (reaction 1) furnishes hydrogen chloride, economies could be realized if this by-product were utilized as a source of chlorine in the chlorination of benzene. This has been accomplished by the Raschig process, which combines the principle of the Deacon process—the preparation of chlorine from hydrogen chloride and oxygen—with the chlorination of benzene and the subsequent vapour-phase hydrolysis of chlorobenzene. The process uses air as the source for oxygen and is operated on a large scale. The individual reactions can be summarized by the equation

$$C_6H_6 + \tfrac{1}{2}O_2 \rightarrow C_6H_5{\cdot}OH$$

In the cumene process (used commercially since 1950), benzene is treated with gaseous propylene in the presence of an acidic catalyst such as aluminum chloride or phosphoric acid on a clay support. After neutralization the resulting reaction mixture is distilled to separate monoisopropylbenzene (called cumene) from polyisopropylbenzene and unconverted benzene. The cumene is then subjected to air oxidation until about one-third is converted to cumene hydroperoxide. The excess cumene is removed from the oxidation mixture by distillation at reduced pressure and recycled. The residue contains the concentrated cumene hydroperoxide and is contacted with a strong acid whereupon it decomposes into phenol and acetone. These reactions are shown by the equations:

$$C_6H_6 + C_3H_6 \rightarrow C_6H_5CH(CH_3)_2$$
$$C_6H_5CH(CH_3)_2 + O_2 \rightarrow C_6H_5C(CH_3)_2OOH$$
$$C_6H_5C(CH_3)_2OOH \rightarrow C_6H_5OH + (CH_3)_2CO$$

The final products, phenol and acetone, are separated by fractional distillation.

PHENOMENALISM (from the Greek *phainomenon*, "appearance", *see* PHENOMENON), a philosophical theory of perception and the external world. Its essential tenet is that propositions about material objects are reducible to propositions about actual and possible sensations, or sense data, or appearances. According to the phenomenalists, a material object is not a mysterious something "behind" the appearances which we experience in sensation. If it were, the material world would be unknowable; indeed, the term "matter" itself would be unintelligible unless it could somehow be defined by reference to sense experiences. In a phenomenalistic analysis of material-object propositions, it is of course essential to mention possible sensations and not merely actual ones. The wall which someone sees just in front of him is hard and rough, though he is not at the moment touching it. But it is still true that, if he were to stretch out his hand, he would experience tactual sensations of hardness and roughness. These tactual sensations are possible, though not at the moment actual. Moreover, material objects continue to exist at times when they are not being observed at all. For instance, there is a fire burning in the next room, though no one at present sees or feels it. But it is still true that, if there were an observer in the next room, he would experience bright, flickery, yellowish colour-patches, and he would feel warmth. Moreover, the precise character of the visual sensations which he would experience and, likewise, the degree of warmth which he would feel would vary with the point of view which he occupied in the room. In speaking about a material object, then, we must be referring to a very large group or system of many different possibilities of sensation. Whether actualized or not, these possibilities continue during a certain period of time. When the object is observed, some of these possibilities are actualized, though not all of them. So long as it is unobserved, none of them are actualized. In this way, the phenomenalist claims, we can give an "empirical cash-value" to the concept of matter, by analyzing it in terms of sensations.

It must be emphasized that the term "possible sensation," as phenomenalists use it, is a kind of shorthand for a hypothetical ("if . . . , then . . .") proposition. When it is said that a visual sensation of such and such a kind is possible, though not actual, the meaning is that a colour sensation of that kind would occur if there were an observer at such and such a place where there is in fact no observer.

Some of the classical difficulties of phenomenalism arise directly from the central part which these hypothetical propositions play in the phenomenalist analysis. The phenomenalist claims to analyze all material-object expressions in terms of actual and possible sense experiences. But it is difficult for him to avoid using material-object expressions in his if-clauses, and this would make his analysis circular. In the example just given, "an observer" (*i.e.*, an animate human organism) is a material-object expression, and so is "in the next room." No doubt we might attempt to analyze each of these material-object expressions in terms of other possible sense experiences. "The next room," for instance, might be resolved into the visual and other sensations which an observer would have if he opened the door or looked through the window. Expressions referring to an observer might be analyzed in terms of the sensations which another observer would have if he were to look in a certain direction. But now the same difficulty arises again about these new if-clauses. A second and even

more important objection is this: it is very difficult to believe that categorical propositions about material objects (*e.g.*, "there is a fire in the next room") can be analyzed without remainder into sets of hypotheticals; *i.e.*, that a statement about what there actually is can be reduced to a set of statements about what there would be if certain (nonexistent) conditions were to be fulfilled.

PHENOMENOLOGY is, in the 20th century, mainly the name for a philosophical movement whose primary objective is the direct investigation and description of phenomena as consciously experienced, without theories about their causal explanation and as free as possible from unexamined preconceptions and presuppositions. The word itself is much older, going back at least to the 18th century, when Johann Heinrich Lambert (*q.v.*), in his *Neues Organon* (1764), applied it to that part of his theory of knowledge which distinguishes truth from illusion and error. In the 19th century it became associated chiefly with Hegel's *Phänomenologie des Geistes* (1807), which undertook to trace the development of the human spirit from mere sense-experience to "absolute knowledge." The so-called Phenomenological Movement did not get under way until the first decade of the 20th century. But even this new phenomenology includes so many varieties that a fair picture requires a brief sketch of its development.

ORIGIN AND DEVELOPMENT

Husserl's Early Phenomenology.—Phenomenology was not founded: it grew. Its fountainhead was Edmund Husserl (*q.v.*). Yet even for Husserl the idea of phenomenology as a new method destined to supply a new foundation for both philosophy and science developed only gradually and kept changing to the very end of his career. Trained as a mathematician, Husserl was attracted to philosophy by Franz Brentano (*q.v.*), whose descriptive psychology seemed to offer a solid basis for a scientific philosophy. The failure of Husserl's first work, *Philosophie der Arithmetik* (1891), to secure an adequate foundation for mathematics, in combination with the strictures of Gottlob Frege (*q.v.*), resulted in Husserl's systematic examination and repudiation of "psychologism," the attempt to use empirical psychology as the ultimate basis for logic. Nevertheless, the "pure logic," which Husserl now outlined at the end of the "Prolegomena" for his *Logische Untersuchungen* (1900), still required, in his thinking, a parallel study of the acts in which the ideal structures of such a logic were given. So the second volume of this epoch-making work consisted largely of "phenomenological analyses," exploring these acts in their essential structures, in contrast to the merely empirical investigation of their factual modifications studied by psychology.

The most important of these painstaking studies dealt with Brentano's concept of intentionality, the main feature by which he had tried to distinguish psychological from physical "phenomena" (taking this term in the wide sense given it by the Newtonian and positivist tradition). But while for Brentano the "intentional relation" meant merely the reference of our perceiving, judging, or loving acts to their perceived, judged, or loved objects, Husserl found in these acts a much richer structure. Thus in our perceiving of this printed page he would distinguish not only the seeing and the seen but also the perspective aspects through which this page appears and its modes of clarity, and he would study the ways in which consciousness relates and synthesizes the various appearances as they refer to the identical object, the page. Husserl also distinguished between "empty" intentional references and those fulfilled with intuitive content (*Anschauung*), which alone could justify such intentions epistemologically. Besides, these intuitive acts were no longer confined to sense-experience. Even the correlates of such logical connectives as "and," "or," and "if" could be given in a nonsensuous or "categorial" intuition, an extension which opened the way for the recognition of the intuitive givenness of such phenomena as relations, essences, values, and other phenomena, both real and ideal.

Only in the years after the publication of these studies did Husserl develop the idea of phenomenology as a universal foundation of philosophy, capable of converting it into a "rigorous science," a science consisting in the descriptive exploration of the essential structures of the directly given, free on the one hand from the unexamined assumptions of a "naturalism" restricted to the empirical natural sciences, and on the other hand from the relativism implied in the historicism of the *Geisteswissenschaften*. This new scientific philosophy was, however, not meant to supply the cheap comforts of a complete *Weltanschauung* or a speculative metaphysics.

Husserl's Pure or Transcendental Phenomenology.—The development of a rigorous or "pure" phenomenology as the science of the essential structures of consciousness by means of correlated studies of the intentional act (*noesis*) and its objective referent (*noema*) involved for Husserl a systematic effort to purify the phenomena of all merely factual ingredients, as studied by the empirical sciences, and of all constructive interpretations. To this end he developed his technique of the "reductions," among which the phenomenological or "transcendental" reduction was the decisive one. Beginning with the suspension of belief in the reality of what seems to be immediately given, like the present printed page, and neither denying nor even doubting its existence, the reductive procedure (*epoché*) aimed at isolating first the field of pure phenomena given with absolute certainty. This field would include each reader's own ego, his acts of reading, and the page as read with all the complexities of its modes of givenness. This immanent region of absolute subjectivity thus coincided for Husserl largely with Descartes' sphere of the indubitable ego, its cogitating acts, and the objects of cogitation insofar as cogitated. Adopting Kantian terminology, Husserl also called this immanent region the transcendental consciousness, as distinguished from its transcendent counterpart, the objects of the real world, such as the page meant as part of the real world beyond consciousness. As to this transcendent world, the reduction was to uncover the otherwise hidden ways by which it was constituted in our consciousness, either passively, as it happens in the perceptual experience of this physical page, or actively, as it takes place in predicative judgments or in the constitution of the sense of the sentences as read on this page. Such "constitutive phenomenology" provided Husserl with the main evidence for his peculiar "transcendental idealism" (to be distinguished from Berkeley's idealism with its basis in the empirical mind), according to which the transcendent objects owe not only their being known but also their very being to the constituting acts of transcendental consciousness. Although even other transcendental egos were supposed to be constituted in each one's own consciousness, Husserl believed that he could avoid solipsism by the introduction of peculiar acts of "appresentation," which attested the equal rights of other transcendental egos. The outcome was a "metaphysical" framework for which Husserl adopted the Leibnizian term "monadology."

In his later philosophizing, consisting largely in the production of a vast number of research manuscripts, Husserl tried to refine especially his studies of the consciousness of time, to which he attributed fundamental importance for the understanding of the structures of all consciousness. But he also sought to open new avenues into his transcendental phenomenology. The one which proved most fruitful was the study of the immediate life world (*Lebenswelt*) of the individual with the ego at its centre, as distinguished from the uncentred objective world of modern science, which, however, was supposed to have sprung from it. This life world was to provide guides for the study of transcendental consciousness.

The Phenomenology of Essences.—A different type of phenomenology, the phenomenology of essences, developed from a tangential continuation of the phenomenology of the *Logische Untersuchungen*. Its supporters were Husserl's students in Göttingen and a group of young philosophers in Munich, originally students of Theodor Lipps (1851–1914), who had turned away from the latter's psychologism and discovered in Husserl powerful support. The Phenomenological Movement, which now began to take

shape, found its most tangible expression in the issuance of the *Jahrbuch für Philosophie und phänomenologische Forschung* (1913–30), a phenomenological yearbook under Husserl as main editor, whose preface defined phenomenology in terms of a return to intuition (*Anschauung*) and to the essential insights (*Wesenseinsichten*) derived from it as the ultimate foundation of all philosophy.

The 11 volumes of the *Jahrbuch* contained, in addition to Husserl's own works, the most important production of the movement in the broader sense. Of the co-editors, Alexander Pfänder (1870–1941) contributed chiefly to the development of phenomenological psychology and pure logic, but developed also the outlines of a complete phenomenological philosophy. Moritz Geiger (1880–1937) applied the new approach particularly to aesthetics, Adolf Reinach (1883–1917) to the philosophy of law. But the most original and dynamic of Husserl's early associates was Max Scheler (*q.v.*), who had joined the Munich group and who did his major phenomenological work in ethics, where he applied it particularly to the problems of value and oughtness. The Polish philosopher Roman Ingarden (1893–) did major work in structural ontology and analyzed the structures of various works of art in its light, while Hedwig Conrad-Martius (1889–) worked intensively in the ontology of nature. Wilhelm Schapp, Jean Hering, Edith Stein, and others have made comparable contributions to various other fields of philosophy. None of these early phenomenologists followed Husserl's road to transcendental idealism, while some tried to develop a phenomenology along realistic lines.

Heidegger's Hermeneutic Phenomenology.—Phenomenology took a new turn in 1916, when Husserl moved to Freiburg im Breisgau, where he was assisted chiefly by Ludwig Landgrebe (1902–) and Eugen Fink (1905–), who, however, emancipated themselves after Husserl's death. But the main event was the adoption of phenomenology by Martin Heidegger (*q.v.*), who had been trained in scholastic philosophy and in the Neo-Kantianism of Heinrich Rickert. Approaching what was for him the supreme question, that of the meaning of beingness (*Sein des Seienden*) through an analysis of the being which we ourselves are (*Dasein*), Heidegger saw in phenomenology the most promising way to uncover the categories of human existence (*existentialia*) for a "fundamental ontology." However, since neither Husserl's phenomenology of transcendental reduction nor the phenomenology of essences proved adequate to this task, he developed a new "hermeneutic phenomenology" designed to interpret the ontological meanings of such human conditions as being-in-the-world, anxiety, and care, with results as startling as they were original.

References to phenomenology nearly disappeared from Heidegger's publications after he had abandoned the completion of his magnum opus, *Sein und Zeit* (1927), for a variety of reasons, which involved not only his estrangement from Husserl, who was disappointed in Heidegger as his academic successor for not continuing his own transcendentalism, but also the failure of the approach to being via human existence to yield the final answer to his basic question. Still, even in his later works Heidegger claimed the "essential help of phenomenological seeing," much as his methods of philosophizing were otherwise changed.

Phenomenological Existentialism in France.—Phenomenology underwent further changes when it was adopted by French philosophy in the form of phenomenological existentialism, a merger which had not yet taken place in Germany, where Karl Jaspers had opposed his philosophy of existence, with its existential appeal to the individual, to phenomenology, with its claims to scientific rigour. Its first French practitioner, Gabriel Marcel (1889–), inspired primarily by Scheler, spoke of phenomenology in the context of his metaphysical meditations on human existence, using it as an aid in exploring concrete situations and such experiences as hope, which had been neglected by scientific psychology and more objectivist philosophies. Jean Paul Sartre (*q.v.*) found in Husserl's phenomenology the effective method for his descriptive explorations of the imagination and the emotions. He moved, however, closer to Heidegger's version in his "essay on phenomenological ontology," *L'Être et le néant* (1943). But even then Sartre defined existence in terms of Husserl's consciousness, rather than Heidegger's *Dasein*, though he rejected Husserl's transcendental idealism as an account of being, the essentially opaque counterpart of consciousness.

Phenomenology became even more central in the philosophy of Maurice Merleau-Ponty (1908–61), whose *Phénoménologie de la perception* (1945) was the most original achievement of French phenomenology of its time. Starting from Husserl's late phenomenology of the life world, Merleau-Ponty anchored the phenomena of perception in the phenomenology of the lived body, in which the perceiving subject was incarnated, as the mediating link to the phenomenal world. Such a phenomenology of human "presence" in the world was also to offer an alternative to the rigid disjunction between idealism and realism, in which consciousness and the world could be reciprocally related. Phenomenology thus became a way of showing the essential involvement of human existence in the world, starting with everyday perception. Important uses of phenomenology can also be found in Paul Ricoeur's *Philosophie de la volonté* (1950–) and Mikel Dufrenne's *Phénoménologie de l'expérience esthétique* (1953).

Dissemination and Influence.—Phenomenology also spread to countries other than France, but there its contributions were less original and substantial, and its modifications less pronounced. However, in Belgium, seat of the Husserl Archives in Louvain since the salvage of Husserl's papers from the Nazis, in the Netherlands, Switzerland, Italy, Spain, and the Latin-American countries, where José Ortega y Gasset introduced it, phenomenology became a major philosophical trend. It was less successful in the Anglo-American world, particularly in England, where it was soon eclipsed by the more congenial philosophy of Ludwig Wittgenstein, although the efforts of such philosophers as J. N. Findlay produced signs of renewed interest. Even in the United States, where Marvin Farber gained a hearing for it in the late 1930s, it never became fully naturalized, though John Wild's phenomenology of the life world gave it new impetus. It also influenced greatly such established international philosophies as Neo-Thomism (Albert Dondeyne).

Of greater significance is the role of phenomenology outside philosophy proper in stimulating or reinforcing phenomenological tendencies in such fields as mathematics (Oskar Becker, Moritz Geiger, Hermann Weyl) and the biological sciences (F. J. J. Buytendijk). Much stronger was its impact on psychology, where Franz Brentano and Carl Stumpf had prepared the ground and where William James, the Würzburg school, and the Gestalt psychologists had worked on parallel lines: apart from the philosophical phenomenologists interested in psychology, David Katz, Johannes Linschoten, and C. G. Graumann may serve as examples. But phenomenology has probably made its strongest contribution to psychopathology, where Karl Jaspers stressed the importance of phenomenological exploration of the patient's subjective experience, and was followed by Ludwig Binswanger, Eugène Minkowski, Viktor von Gebsattel, Erwin Straus, and others. The phenomenological strand is also very pronounced in American existential psychiatry, as promoted chiefly by Rollo May. Phenomenology has also affected sociology (Felix Kaufmann, Alfred Schutz), history (Raymond Aron), and the study of religion (Max Scheler, Rudolf Otto, Friedrich Heiler, Gerardus van der Leeuw, Paul Tillich).

CHARACTERISTICS

Considering the variety of phenomenologies which have thus issued directly or indirectly from Husserl's inspiration, it is not easy to find a common denominator for such a movement beyond its common source. But similar situations occur in other philosophical and nonphilosophical movements. Although, seen from Husserl's last perspective, all departures from his own could not but appear as heresies, a more generous view will show that all those who consider themselves as phenomenologists subscribe, for instance, to his watchword "To the Things" (*Zu den Sachen*), meaning by it a fresh approach to the concretely experienced phenomena, as free as possible from conceptual presuppositions, and an attempt to describe them as faithfully as possible. Besides,

most adherents to phenomenology will hold that it is possible to obtain insights into the essential structures and the essential relationships of these phenomena on the basis of the careful study of concrete examples supplied by experience or imagination and by systematic variation of these examples in the imagination. Some phenomenologists also stress the need of studying the ways in which the phenomena appear in our intentional consciousness. Beyond this merely static aspect of appearance some also want to investigate its genetic aspect, exploring, for instance, how the phenomenon intended, say, a book, constitutes itself in the typical unfolding of our experience. Husserl himself believed that such studies required a previous suspension of belief in the reality of these phenomena, while others consider it not indispensable but helpful. Finally, it should be mentioned that in existential phenomenology the meeting of certain phenomena such as anxiety is explored by a special "hermeneutic" interpretation, whose methodology needs further clarification.

It may also be helpful to bring out the distinctive "essence" of phenomenology by confronting it with some of its philosophical neighbours. In contrast to positivism and traditional empiricism, from which Brentano had started out and with which phenomenology shares the unconditional respect for the positive data of experience ("We are the true positivists," Husserl claimed in his *Ideen*), phenomenology does not restrict these data to the range of sense-experience, but admits on equal terms such nonsensuous data as relations, categorial entities, values, etc., as long as they present themselves intuitively. Consequently phenomenology does not reject universals and recognizes, in addition to the analytic *a priori* and the synthetic *a posteriori*, knowledge of synthetic *a priori* relationships based on insight into essential relationships within the empirically given.

In contrast to phenomenalism (*q.v.*), an epistemological position with which it is often confused, phenomenology, which is not primarily an epistemological theory, accepts neither the rigid division between appearance and reality, let alone a thing-in-itself, nor the narrower view that phenomena are all there is (sensations or permanent possibilities of sensations). These are questions on which phenomenology as such keeps an open mind, pointing out, however, that phenomenalism overlooks the complexities of the intentional structure of our consciousness of the phenomena.

In contrast to a rationalism which stresses conceptual reasoning at the expense of experience, phenomenology insists on the intuitive foundation and verification for all formal concepts, and especially for all *a priori* claims; in this sense it is a philosophy "from below," not "from above."

In contrast to an analytic philosophy which substitutes simplified constructions for the immediately given in its complexity and applies "Ockham's razor," phenomenology resists all transforming reinterpretations of the given, analyzing it for what it is in itself and on its own terms.

In contrast to linguistic analysis, with which however phenomenology shares its respect for the distinctions of the phenomena reflected in the shades of ordinary language as at least one possible starting point for phenomenological analyses, phenomenology does not think that the study of ordinary language is a sufficient basis for studying the phenomena in all their complexity, which ordinary language cannot and need not try to exhaust.

In contrast to an existential philosophy which believes that existence is unfit for phenomenological analysis and description, since it tries to objectify the unobjectifiable, phenomenology holds that it can and must deal with these phenomena, however cautiously, as well as with other intricate phenomena outside human existence.

In the third quarter of the 20th century it remained to be seen whether phenomenology could make solid contributions to philosophical knowledge. To this end it needed to develop rigorous standards, which had not always been observed by some of its most brilliant practitioners, such as Max Scheler, and which were apt to be violated in a philosophy whose ultimate appeal had to be made to intuitive verification. With this proviso, phenomenology may well be qualified, not only to become a bridge for better international communication in philosophy but also to shed new light on philosophical problems old and new, to reclaim for philosophy parts of our everyday life world which have been abandoned by science as too private and too subjective, and finally to give access to layers of our experience unprobed in our everyday living, thus providing deeper foundations for both science and life.

BIBLIOGRAPHY.—The *Logische Untersuchungen*, not yet available in English translation, are ably reported on in J. N. Findlay's article "Phenomenology" in the preceding editions of the *Encyclopædia Britannica* and more fully paraphrased in Marvin Farber's *The Foundation of Phenomenology* (1943). The first book of *Ideen zu einer reinen Phänomenologie und phänomenologischen Philosophie* is available in W. Boyce Gibson's not always reliable translation (1931; reissued 1952), the *Cartesianische Meditationen* in the faithful English rendering of Dorion Cairns (1960). The *Husserliana* edition of the Husserl Archives (1950 ff.) in its early volumes emphasized previously unpublished materials but will eventually include all of Husserl's works. Husserl's article "Phenomenology" in the 1929 edition of *Encyclopædia Britannica* (retained until 1956) appears in the light of the German original (*Husserliana* IX) as an over-condensation by the translator which cannot claim to be an authentic text.

References to the major works of the phenomenological movement in the original and translation and to the secondary literature, especially in English, can be found in H. Spiegelberg, *The Phenomenological Movement*, 2nd ed. (1965); *see* also works cited in the article HUSSERL, EDMUND. Most of the original German studies on phenomenology appeared in the *Jahrbuch für Philosophie und phänomenologische Forschung* (1913–30). The very different U.S. quarterly *Philosophy and Phenomenological Research*, ed. by Marvin Farber, occasionally publishes articles related to phenomenology. (HE. SP.)

PHENOMENON (Greek *phainomenon*, from *phainesthai*, "to be shown," "to seem," "to appear"), any object, fact, or occurrence perceived or observed. The Greek verb *phainesthai* can be used with or without the implication that the thing perceived is other than what it appears to be. Thus in Aristotle's ethics "the apparent good" is what seems good to a man, whether or not it really is good. In general, phenomena are the objects of the senses, sights, and sounds, contrasted with the real objects apprehended by the intellect. In later Greek philosophy phenomena are the observed facts contrasted with the theories devised to explain them. A theory is said to "save the phenomena" if it is consistent with the facts.

This last use became common in the early part of the 17th century when scientists used phenomena for the observed facts that they sought to explain (*e.g.*, astronomical phenomena, the phenomena of gravitation, phenomena of magnetism), a use still current. In modern philosophy the word is sometimes used for what is immediately apprehended by the senses before any judgment takes place; but it has never become a technical term, most philosophers preferring more artificial words such as sense-datum (hence such terms as phenomenalism and phenomenology, *qq.v.*). In English versions of Kant the word is often used to translate *Erscheinung* ("appearance"), Kant's word for the immediate object of sensory intuition, the bare datum which becomes an object only when interpreted through the categories of substance and cause. Kant himself uses it for the object interpreted through the categories as opposed to the noumenon (*q.v.*), or thing-in-itself, to which the categories do not apply. (P. H. N.-S.)

PHERECYDES OF SYROS (fl. *c.* 550 B.C.), Greek mythographer and cosmogonist, who is traditionally associated with the Seven Wise Men of Greece, especially with Thales. He was the son of Babys and is to be distinguished from the genealogist Pherecydes of Athens, who lived about a century later. The earliest known reference to Pherecydes of Syros is in the 5th-century poet Ion of Chios. The belief that he was responsible for a *heliotropion* (a means of marking the "turning-point" of the sun at the solstice) on the island of Syros made some connect him with a line in the *Odyssey* (xv, 404) and place him earlier than Homer; but tradition made him the teacher of Pythagoras. The same miracles were ascribed to both, and this may be the reason why Cicero (*Tusculan Disputations*, i, 16, 38) and Augustine (*Contra Academicos* iii, 17; *Epistle* cxxxvii, 12) say that he first taught the immortality of the soul. He was also credited with the doctrine of metempsychosis.

Aristotle (*Metaphysics* 1091 b 8) characterized Pherecydes' work as a mixture of myth and philosophy. His book the *Heptamychos*

(L. Preller's correction *Pentemychos* is probably unnecessary), of which only a few fragments remain, described the origin of the world and the loves and battles of the gods. Despite its mythical form, it has features reminiscent of 6th-century Ionian speculation; for instance, the god Time creates three elements, fire, air and water, which Zeus-Eros unites to form a cosmic system. Allegory is prominent, as in the names of the gods and in a fragment describing a robe embroidered by Zas (Zeus) for his bride Chthonie (Earth) with representations of earth and ocean. Its philosophical tendency and its prose form distinguish the work from most of the rich cosmogonical literature of the 7th and 6th centuries B.C. (*e.g.*, the theogonies of Hesiod and of the pseudo-Orpheus); some critics have seen the influence of Anaximander in both features.

See O. Kern, *De Orphei, Epimenidis Pherecydis theogoniis* (1888); H. Diels and W. Kranz, *Die Fragmente der Vorsokratiker*, 3 vol., 7th ed. (1954). (W. K. C. G.)

PHETBURI, a province of peninsular Thailand lying between the Gulf of Thailand and southern Burma. The eastern part, especially astride the middle course of the Phetburi River, contains areas of productive alluvial soils which produce rice, coconuts, and palm sugar. Irrigation, however, is necessary. The topography of the western part is mountainous and heavily forested. Area 2,454 sq.mi. (6,359 sq.km.); pop. (1960) 237,853.

Phetburi (pop. [1960] 24,654), the capital, is near the mouth of the Phetburi River, 93 mi. (150 km.) SW of Bangkok by rail.

In ancient times before the sea route through the Straits of Malacca and around the Malay Peninsula was developed, Phetburi was the eastern terminus of an overland trade route from India and Europe to continental southeastern Asia. Ruins of ancient Brahman and Buddhist temples and caves are found in the environs; also a palace built by King Mongkut and one built by his son King Chulalongkorn. (T. F. B.)

PHIDIAS (Pheidias) (active from about 475 to 430 B.C., or later), an Athenian, the son of Charmides and pupil of Hegias, may be regarded as the greatest of Greek sculptors. Among his early works, the most important were a bronze group at Delphi (perhaps *c.* 465), erected as a memorial after the battle of Marathon; a gold and ivory statue of Athena in Achaea; and the famous bronze Athena on the Athenian Acropolis, also a thank offering after Marathon, but not set up until *c.* 456 (*cf., Hesperia,* xv, pp. 106 ff.; 1946).

When Pericles rose to power (449) and initiated a great building program in Athens, Phidias was put in charge of all artistic undertakings (*see* Plutarch, *Perikles*). Phidias himself made the gold and ivory statue of Athena, about 40 ft. high including its base, that stood inside the Parthenon and was dedicated in 438.

According to Pausanias' *Description of Greece* (I. 24, 6), the goddess stood erect, wearing a tunic, aegis and helmet, a winged victory on her extended right hand, a spear in her lowered left; by her side were a shield and a serpent; base, shield and helmet were adorned with figures. From this description a number of copies have been identified, notably the Varvakeion and Lenormant statuettes in Athens, the Strangford shield in London and the reliefs found in the sea off the Piraeus.

Though Phidias himself could not have executed the sculptures of the Parthenon—the 92 metopes, the frieze about 170 yards long and the two pediments—it seems probable that he was responsible for their design. Much of the sculptural decoration has survived (now mostly in London, Athens and Paris; a few pieces in the Vatican). Since they are Greek originals, these remains show the style of Phidias better than a host of Roman copies. (*See* Parthenon.)

Phidias' foremost work, in the estimation of the ancients, was the gold and ivory statue of Zeus, about seven times life-size, that he made for the temple at Olympia. It was considered the greatest religious statue of Greece, and Quintilian (*Institutionum Oratoriarum,* XII, 10, 9) says that "its beauty can be said to have added something to traditional religion." All that now remain are the description by Pausanias, small reproductions on Roman coins and terra-cotta moulds used for the drapery. Zeus was shown seated on a throne, holding a Nike in his right hand and a sceptre in his left. All parts of the statue, even the sandals, were richly decorated.

After long discussion among modern archaeologists, it is now agreed that Phidias made the Athena Parthenos earlier than the Olympian Zeus; for the moulds from Olympia, which were found in a dump adjoining what was described by Pausanias as Phidias' workshop, and which had evidently been used for hammering into them the gold for the draperies of Zeus and Nike, indicate a style in the 430s rather than the 450s.

Besides his two masterpieces, ancient writers mention a number of other statues by Phidias, all now lost. The most credible identifications are: The Lemnian Athena, set up on the Acropolis and famous for its beauty, which is perhaps reproduced in a head in Bologna and a statue in Dresden; the Apollo Parnopius, also erected on the Acropolis, perhaps reproduced in the Cassel Apollo; the Anadumenus of Olympia, perhaps reproduced in the Farnese Diadumenus of the British museum; and the Amazon—made in competition with Polyclitus, Cresilas, Cydon and Phradmon (*cf.,* Pliny, *N.H.,* xxxiv, 53)—probably reproduced in a number of copies, all headless, of which the best-preserved is that found in Hadrian's villa, near Rome.

From these works one can gain some idea of Phidias' style. Quiet stances, serene expressions and a certain majesty of conception characterize his single figures; even when movement is represented in some of his reliefs, a monumental quality is imparted. Though the construction of the human body is perfectly understood, its rendering is restrained and harmonized. In other words, Phidias may be called the initiator of the idealistic, classical style that distinguishes Greek art in the later 5th and the 4th century B.C., after the experimental epoch of Myron and his associates, and before the advent of the realistic Hellenistic age. And this idealistic quality—expressed in restrained modeling and in elevation of spirit—is still considered typical of Greek art.

Phidias was also a painter, an engraver and a worker in embossed metalware. His chief pupils were Alcamenes, Agoracritus and Colotes.

Buschor, *Phidias der Mensch* (1946); G. M. A. Richter, *The Sculpture and Sculptors of the Greeks,* rev. ed., pp. 215–228 (1950), and *Three Critical Periods in Greek Sculpture,* pp. 1–14 (1952); G. Lippold, *Die griechische Plastik,* pp. 141–157 (1950); G. Becatti, *Problemi fidiaci* (1951); S. Liegle, *Zeus des Pheidias* (1952); E. Kunze, *Gnomon,* p. 222 ff. (1955) and p. 318 ff. (1956), on the molds from Olympia. Lippold and Becatti give extended bibliographies of the earlier writings. (G. M. A. R.)

PHIGALIA (Phialia), an ancient Greek city on the Neda River in southwest Arcadia. It stood on a high plateau between deep ravines, along which were defensive walls and towers in part still standing. The modern village of Figalia (formerly Pavlitsa) is at the southwestern corner of the ancient site. This remote fortress left only an inconsiderable record in the general history of Greece, but Pausanias, writing in the 2nd century A.D., noted some religious peculiarities, occult practices, and strange gods such as probably existed elsewhere in Arcadia. He describes the horse-headed Black Demeter, whose sanctuary was a cave, and the fish-tailed Artemis Eurynome.

The distinction of Phigalia in ancient as in modern times comes from its Temple of Apollo Epikourios ("the Helper") at Bassae, 4 mi. NW of the city on a high and desolate terrace of Mt. Cotilius. Pausanias says that it was the finest temple in the Peloponnese after that of Artemis at Tegea. It is now the best-preserved temple in Greece after the Parthenon and the Temple of Hephaestus (the so-called Theseum) at Athens. Pausanias also says that it was dedicated to Apollo by the Phigalians in gratitude for his protection during a plague and that its builder was the Athenian Ictinus, the architect of the Parthenon. The Peloponnesian states were then at war with Athens, but Ictinus could have worked in Arcadia during the short Peace of Nicias (421–418 B.C.), and this date agrees with the style of the architectural sculpture. The plan and structure of the temple were in many respects unique (*see* Greek Architecture: *The Culmination at Athens [450–400 B.C.]*).

BY COURTESY OF THE TRUSTEES OF THE BRITISH MUSEUM

SOUTH FRIEZE OF THE TEMPLE OF APOLLO AT BASSAE, NEAR PHIGALIA, SHOWING THE COMBAT OF THE GREEKS AND AMAZONS; 5TH CENTURY B.C. IN THE BRITISH MUSEUM

The site was first explored in 1812 by the young English architect C. R. Cockerell and a party of traveling companions. Thirty-five of the original 38 exterior columns were then standing, with most of their architraves, but the interior columns had fallen with their frieze, which was buried under fragments of roof and walls. The frieze, which was found complete or nearly so, was removed, shipped to Zante, there put up to auction, and bought by the British Museum.

The material of the temple is the local limestone, but the frieze is a coarse marble. It consists of 23 slabs two feet high making a total length of 101 ft. Two conventional subjects are represented in high relief, the Battles of Lapiths and Centaurs and of Greeks and Amazons. The style is both dynamic and affected: violent and realistic motion in the figures, and fanciful exploitation of taut or flying draperies. It is the first appearance of the mannered style which is refined in the Victory of Paeonius at Olympia and later in the Amazon frieze of the Mausoleum at Halicarnassus. The execution of the Bassae frieze is inferior to the design. It was evidently cut by several provincial masons working from large detailed drawings. If the architect was Athenian, it may be assumed that the drawings came from Athens, and the assumption is supported by the relation of the style to Attic vase paintings and by the fact that the subjects represented were Attic versions of the myths. The protagonist in both battles seems to be Theseus, who is certainly the central figure of the Amazonomachy, marked by his club and lionskin. This scene is therefore the Amazons' attack on Athens, which was said to have ended in a formal peace. That happy issue may be indicated in the frieze by some friendly advances made by combatants of both sides toward their opponents. Such touches of humanity, and the pain and pity shown by facial expression, were a novel element in Greek art and here perhaps unique in sculpture.

PHILADELPHIA: *see* AMMAN, Jordan.

PHILADELPHIA, the largest city of Pennsylvania, U.S., known primarily, perhaps, for its high place in U.S. history, but also one of the principal cities of the northeastern United States. In the first part of the 20th century it showed one of the most rapid rates of population growth among the major U.S. cities; its industrial growth was proportionately high and it became a leader in devising redevelopment programs to deal with the urban problems characteristic of the 20th century. The city, which is coextensive with Philadelphia county, is at the confluence of the Delaware and Schuylkill rivers about 83 mi. (134 km.) S.W. of the centre of New York city and about 126 mi. (203 km.) N.E. of the centre of Washington, D.C.

The 1950 population of the city proper was 2,071,605, a 14.6% increase over the 1940 population. Like most other large U.S. cities, Philadelphia lost population in the following decade; the 1960 census figure was 2,002,512, a decrease of 3.3%. For comparative figures for selected years, *see* table in PENNSYLVANIA: *Population*. The 1960 population of the standard metropolitan statistical area, which includes Bucks, Chester, Delaware, Montgomery and Philadelphia counties in Pennsylvania and Burlington, Camden and Gloucester counties in New Jersey, was 4,342,897, an 18.3% increase over 1950. Within the standard metropolitan statistical area are the cities of Chester and Norristown (*qq.v.*) in Pennsylvania and Camden (*q.v.*) in New Jersey. The suburbs reach out far to the north and south virtually to meet those of New York city and Baltimore, for Philadelphia is a part of the almost unbroken urbanized region which has come to extend along the Atlantic coast from Maine to Virginia.

Philadelphia's eminence resulted to a large extent from its geography. Its central and oldest section lies on a peninsula between the Delaware and Schuylkill rivers. Although it is 88 nautical miles (75 statute miles) from the Atlantic ocean, the broad Delaware river and bay ensured ready access to the sea and made the city one of the leading U.S. seaports. Furthermore, Philadelphia occupies the place where the principal roads from New York city southward run close to the Delaware just after crossing it; an Indian trail followed this route even before the coming of the white men. Thus the city is important to inland as well as to nautical communication. The valleys of the Schuylkill and of other tributaries to the Delaware, finally, have always given Philadelphia avenues to the rich agricultural, mining and industrial areas of eastern Pennsylvania.

From the peninsula between the Delaware and the Schuylkill, where the centre of the city lies, Philadelphia stretches north and south along the Delaware to a total river frontage of 23.7 mi. (38.1 km.). Inland its extension varies from 5 to 15 mi. (8 to 24 km.). The topography of the city is largely of a sort more characteristic of New Jersey than of the Pennsylvania hills to the west, since much of it occupies the Atlantic coastal plain. The southern extremity, the Tinicum lowland, is protected by dikes, for in places it is more than 5 ft. (1½ m.) below high tide. The greatest part of the coastal plain rises gradually from the Delaware to a height of about 150 ft. (46 m.) above sea level at the fall line. There, in the western extremities of the city, communities such as Roxborough and Chestnut Hill climb hills of the Piedmont plateau, reaching an elevation of about 400 ft. (122 m.).

History.—Of the important Atlantic coastal cities, Philadelphia was the last to be established, in part because navigation of Delaware bay and the Delaware river presented severe problems to early mariners. The entrance to the bay was a dangerous open roadstead, which until the building of the immense Delaware breakwater in the early 19th century continued to claim hundreds of ships. The channel of the bay and river were uncommonly intricate, so that even after numerous improvements, Delaware pilots are often known as the most skilful on the Atlantic coast.

Giovanni da Verrazano may have seen Delaware bay in 1524 and Henry Hudson is known to have reached its mouth in 1609. Thereafter various explorers traveled up the bay and the river until sufficient interest was stimulated to lead to settlement attempts by the Dutch and the English in the 1630s. The first permanent white settlements in what is now Philadelphia were planted in the 1640s by the Swedes, whose interest in the region had been aroused by certain dissidents from the Dutch West India company who believed their company had not been sufficiently energetic in exploiting the Delaware country. In 1655 New Sweden surrendered to a Dutch expedition from New Amsterdam, but from the brief Swedish colonial effort came a population of

about 2,000 Swedes and Finns who inhabited the Delaware area by the 1680s, including the community in what is now South Philadelphia which was later to build Old Swedes' church.

The reign of the Dutch also proved brief, ending when New Netherland surrendered to the English in 1664. Thereafter the early history of the city of Philadelphia is inseparable from that of the state. (*See* also PENNSYLVANIA: *History.*) On March 4, 1681, William Penn received from Charles II, out of friendship with the king and the duke of York and in payment of a debt of £16,000 owed by the king to Penn's father, his charter for a colony to lie north of Maryland and west of the Delaware. As a Quaker leader, Penn planned in his colony a "Holy Experiment," where men of his own religious sect and of other persuasions might find freedom of the mind. Soon he sent out surveyors who were to plat a city along the river, which Penn envisioned as the capital and metropolis of his colony. He instructed the surveyors to choose a high, dry and healthy site, one where ships might well ride, and if possible one where a navigable creek flowing into the Delaware would lend further encouragement to commerce. When the surveyors reached Pennsylvania, they found such a site at the peninsula formed by the flow of the Schuylkill into the Delaware. The Lenni-Lenape Indians of the area called this place Kué-quenâku or, as the white men more commonly rendered it, Coaquannock, meaning "grove of tall pines." Penn, however, had already selected his own name, one with both classical and biblical associations and with a meaning appropriate to his purpose: Philadelphia. Passages in the Book of Revelation refer to the city of Philadelphia in Lydia in Asia Minor. That city was worthy of remembrance as the seat of one of the seven early Christian churches, and its name signified brotherly love.

Penn enjoined his surveyors and other agents so to plan Philadelphia that it should be "a greene countrie towne which will never be burnt, and always wholesome." Each house, Penn instructed, ought to be placed in the middle of its plot, with garden, orchards and fields around it. The streets were to be laid out in a straight and regular pattern, reserving spaces for markets and squares—instructions scrupulously obeyed by Thomas Holme, Penn's surveyor general. Holme's town plan formed a perfect checkerboard, to which the streets of central Philadelphia have generally continued to adhere.

William Penn himself sailed to his colony and city late in 1682, arriving in the ship "Welcome" inside the Delaware capes on Oct. 24 and proceeding thence, probably by barge from Chester, to Philadelphia. He remained only until the political and business problems of his colony called him back to England in Aug. 1684, but during his brief stay he was able to witness a remarkable growth of his city and colony. His policy of religious freedom together with his astute advertising of the potential wealth of Pennsylvania began to attract a large and multinational immigration which was to make Pennsylvania the prototype of the American melting pot. Swedes and Finns were already present; Englishmen and Welshmen, especially Quakers, came in large numbers; and the interest awakened by Penn's travels in Holland and Germany brought from those areas German Pietists, religiously akin to the Quakers, who were the vanguard of the great German migration to colonial Pennsylvania. Whatever part of Pennsylvania was their destination, most immigrants landed in Philadelphia and many of them stayed there. By the time Penn departed in 1684 there were 357 houses in Philadelphia, many of them "brave brick houses." By the next year, there were said to be 600 houses, and in that year the population of the colony, centring on Philadelphia, was estimated at more than 7,000. When Penn returned to his colony in 1699, for another two-year stay, he found that population growth already had erased his "greene countrie towne." His governors had felt compelled to divide and subdivide the city lots, and many of the owners had done likewise. The rich continued to enjoy lawns and trees but the middle class was coming to live in row houses facing each other across narrow streets, while the workingmen and their families occupied still more constricted quarters, often pressed into the narrow alleys behind the principal streets. As the 18th century began, Philadelphia was becoming the crowded city of narrow red brick houses which it was to be through the revolutionary period. Remains of this period can be seen in such places as Elfreth's alley.

The Metropolis of Colonial America.—By the time of Penn's second visit the economic pattern of 18th-century Philadelphia was becoming plain. Like all the cities of colonial North America, Philadelphia built its economic life upon a commerce aimed at bringing to the new world the manufactured goods of the old world. Philadelphia was well supplied with commercial resources which, as the 18th century progressed, enabled it to become the wealthiest and most populous city of British North America.

For the export trade Philadelphia could draw upon the produce of the fertile farmlands stretching from the Delaware to the Susquehanna and beyond, a region which through the early 18th century filled up with skilful and industrious German farmers and then, farther west, with Scotch-Irish settlers. Wheat, corn, hemp, flax, beef, pork and timber products reached Philadelphia from the Pennsylvania hinterland. By the second third of the 18th century iron furnaces and forges up the Schuylkill and farther west were adding another product to Philadelphia commerce. From the neighbouring provinces of New Jersey and Maryland, from the Delaware counties and in time even from the Shenandoah valley of Virginia came still more agricultural products.

Much of Philadelphia's export trade sailed to the West Indies, where foodstuffs went to the plantations in exchange for sugar, molasses or rum. Directly or indirectly the sugar trade in turn gave Philadelphia merchants staples which they sold in England and there bought manufactured goods. A brisk wine trade developed with the Madeiras. In time of war with France, *i.e.*, continually through Philadelphia's colonial history, many of the West India traders were not above turning to privateering; even certain Quaker merchants seem to have formed connections with privateers. Whether righteous or not, this activity also brought swift increments of wealth. In 1696 the governor of the province reported that "Philadelphia in fourteen years is become equal to the City of New York in trade and riches." Customs receipts increased from £1,500 in 1699 to £8,000 in 1702. By the middle years of the 18th century, Philadelphia was surpassing even Boston in volume of commerce.

Often overlooked, but of equal importance with Philadelphia's West India commerce and more important than its trade with

ELFRETH'S ALLEY, SAID TO BE THE OLDEST RESIDENTIAL STREET IN CONTINUOUS USE IN THE U.S.

Europe, was its coastwise commerce. By the 1730s Pennsylvania had become the granary for the tobacco and rice colonies of the south as well as for the West Indies. In addition and more important, Philadelphia had developed an exceedingly profitable business with New England, which produced neither wheat nor bar iron sufficient to its needs; therefore these products sailed from Philadelphia to the colonies to the north in exchange for merchandise, coins and bills of exchange. In 1752, 103 vessels cleared Philadelphia for New England. The favourable balance of this trade in the mid-18th century amounted to over £52,000 annually.

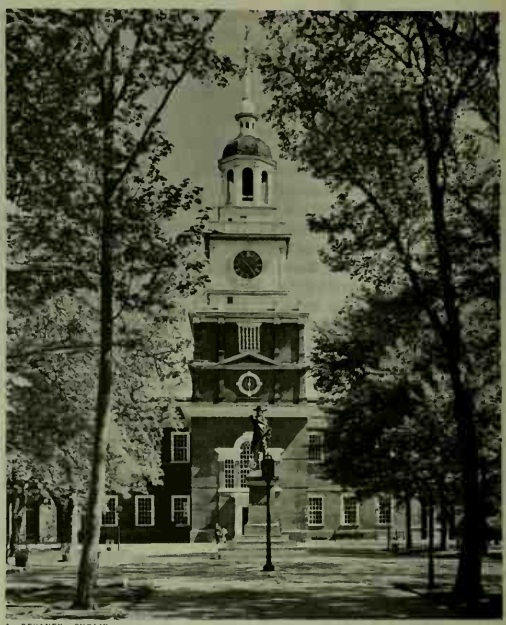
Philadelphia manufactories began to develop both as a result of the city's commercial growth and as a cause of further growth. After 1725 the Delaware valley became a shipbuilding centre; in 1726 the Delaware yards turned out only 7 ships but during the next decade and a half they built 380 vessels. The yards were soon the most extensive in the colonies. The demands of the port stimulated cooperage establishments. Flour mills appeared in the city and in 1690 the first American paper mill began to operate along Wissahickon creek. By 1718 the cordwainers (workers in leather) were numerous enough to incorporate as a craft. Fourteen rum distilleries, three steel furnaces and an anchor forge, four carriage and wagon shops, an establishment for the manufacture of fire engines and a glass works soon appeared. A distinct merchant class developed but there also emerged a growing lower class of mechanics and artisans.

With urban growth came civic improvements. In the mid-18th century Philadelphia ceased to be a wilderness outpost and became a community whose appearance rivaled that of European cities of comparable population. Public street lighting was instituted in 1752 and in the 1760s the streets began to be paved, while 500 public pumps were set up to supply the citizens with water. Public buildings of substantial size began to appear, many of which had grace as well as size and were among the architectural achievements of colonial America. Most notable was the state house, now known as Independence Hall, the construction of which began in 1732. Attorney General Andrew Hamilton had drawn up plans for a civic centre and shared with master carpenter Edmund Woolley the designing of the building itself; in it they gave Philadelphia an imposing structure of balanced masses in the 18th-century style.

During the 18th century the population of Philadelphia spilled beyond the original northern and southern boundaries, Vine street and South street, to form the suburbs of Southwark, the Northern Liberties, Passyunk and Moyamensing. The total population of the city and suburbs grew from 13,000 in 1740 to 22,000 in 1760 and to 40,000 by 1775. By that time Philadelphia was the largest city in the colonies (by about 15,000 persons) and in size probably ranked second only to London among empire cities.

By the 1770s Philadelphia was a centre of learning and culture as well as of trade and industry, not only by American standards but by European as well. Its growth in these directions had once been slow; in the beginning, of course, its settlers were too busy wresting a livelihood from the wilderness to bother with things of the mind, and even as late as the 1720s visitors were impressed with the way in which business swallowed up all other concerns. But a new era was coming. Historians often regard 1726 as marking the beginning of the change, for in that year Benjamin Franklin returned to the city from his first visit to England, still an obscure printer but destined to become the civic leader of Philadelphia and to guide his city into new paths of intellectual achievement. Among his contributions to the cultural life of colonial Philadelphia were his organization of certain alert and ambitious young mechanics of the city into the mutual improvement society which became the Junto; his assistance in the development of the Library Company of Philadelphia, the first subscription library in America, out of the Junto; and his leadership in the foundation of the American Philosophical society and in the establishment and growth of the Philadelphia academy, out of which the University of Pennsylvania was to arise.

But important as he was, Franklin was merely first among equals in a general cultural awakening. The way for Franklin had been prepared (albeit by a man who did not like him) by James Logan, William Penn's secretary, the collector of a private library of more than 2,000 volumes. Among Franklin's Philadelphia contemporaries were the botanist John Bartram, correspondent of Linnaeus; the noted physician John Morgan, first American author on medical education and medical history; Ebenezer Kinnersley, who rivaled Franklin as a pioneer investigator of electricity; and the astronomer David Rittenhouse, a leader in the observations of the transit of Venus across the sun in 1769 which were of great importance in determining the parallax of the sun. In the arts and letters, Benjamin West ventured his first artistic efforts in Philadelphia; Thomas Godfrey, Jr., wrote the first American tragic drama; and the literary circle which formed around Provost William Smith of the College of Philadelphia is worth mentioning if only to call attention to Smith, a man whose personal efforts did much to make Philadelphia an intellectual centre.



A. DEVANEY—PUBLIX

INDEPENDENCE HALL, THE OLD STATE HOUSE ERECTED IN 1732, WITH STATUE OF JOHN BARRY, NAVAL HERO OF THE REVOLUTIONARY WAR

Colonial and Republican Capital.—Its general prominence, together with its central location, led to the selection of Philadelphia as the meeting place of the first continental congress in 1774 and the city embarked on its turbulent revolutionary career. The first continental congress met in Carpenters' hall, and there drew up the continental association and the Declaration of Rights and Grievances, steps which led the colonies almost directly into war against the mother country. In 1775 the second continental congress met in the state house, acknowledged the fighting around Boston by organizing the continental army under the command of George Washington and, by thus embarking on rebellion, took the course which led to the adoption of the Declaration of Independence the following year. The role of Philadelphia as the headquarters of the revolutionary government made it the objective of the British general Sir William Howe's campaign of 1777; after Howe defeated Washington's forces south of the city the congress fled and Philadelphia was occupied by the British through the winter of 1777–78. The continental army camped outside the city at Valley Forge, and fighting occasionally flared up at such places as Germantown and Barren Hill on the outskirts. In the

spring of 1778, a change of generals and of war plans led the British army to evacuate the city and to return across New Jersey to New York, opening the way for the reconvening of the congress in Philadelphia.

The British occupation underlined the fact that the American Revolution made Philadelphia a city much divided within itself. Certain leading families were obviously not unhappy to welcome the British, and many Philadelphians participated gladly in the gay social season which the British officers improvised. Many Philadelphians, like many other Americans throughout the colonies, could not easily abandon the loyalty which as British subjects they had always felt to the crown. Mixed with their emotions of loyalty, furthermore, was the resentment which many members of the upper classes had come to feel toward a Revolution, which in Philadelphia had become peculiarly the cause of the lower classes, the mechanics and artisans. By the opening of the Revolution, Philadelphia society had become distinctly stratified. The growth of commerce had been highly profitable to some Philadelphians and had opened wide economic divisions within the population, so that social and economic leadership was held tightly by a comparatively small group of merchants, professional men and proprietary agents. Political leadership resided in the same hands, since the franchise was limited to men who possessed a freehold estate or personal property to the value of £50. By 1776 only about 1 in 50 of the male inhabitants could cast a ballot. The political power of the upper class further enhanced its economic power, for the city government frustrated competition from below through its regulations of markets, auctioneers and peddlers. When the Revolution broke out, the aristocrats, naturally conservative, hesitated to endorse the movement. But the mechanics, artisans and labourers took advantage of that hesitation to discredit the aristocrats as an unpatriotic class and thus to make the independence movement also a movement for increased democracy. They joined with equally discontented farmers from the back country of Pennsylvania to establish the radical Pennsylvania constitution of 1776, which allowed every adult male taxpayer to vote and hold office in the state government. It was against this background of a rising of the lower classes that much of the Philadelphia aristocracy welcomed the British occupation in 1777.

The end of the occupation brought back to Philadelphia both the continental congress and the ambitious local democratic party, but the withdrawal of the British and the eventual American victory in the Revolution did not open the way for the unmitigated triumph of either group. The continental congress was transformed into the congress of the Articles of Confederation, and during the 1780s that congress, meeting sometimes in Philadelphia but sometimes elsewhere, sank gradually into impotence. The success of the Pennsylvania and Philadelphia democrats in the state constitution of 1776 gradually gave way before a counter-revolution which culminated in the conservative state constitution of 1790. The economic power and social prestige of the Philadelphia aristocracy emerged from the war largely unimpaired, and these elements aimed at a substantial recapture of political power. In 1789 the state assembly passed an act of reincorporation of Philadelphia which was considerably more democratic than the colonial charter but nevertheless favourable to the merchant aristocracy. The vote was restricted to freeholders, who elected 30 common councilmen for three-year terms and 15 aldermen for seven-year terms. The aldermen chose the mayor from among their own number. Significantly, the first mayor under the new government, Samuel Powel, had also been the last mayor under the colonial charter.

As for national affairs the Constitutional Convention laboured in the Philadelphia state house during the summer of 1787 with the Philadelphians Benjamin Franklin and James Wilson among its most influential members. The congress of the new government first met in New York city, but in 1790 it voted to establish the seat of the new government at Philadelphia for ten years before moving to the permanent capital on the Potomac river.

The decade 1790–1800, when Philadelphia was once again the U.S. capital, constitutes something of a golden age in Philadelphia history. Political, economic and cultural leadership of the new nation were all concentrated in Philadelphia. Congress and the U.S. supreme court sat in new buildings flanking the state house. Presidents Washington and John Adams maintained a republican court, centring on the president's mansion on Market street near Sixth, whence Washington proceeded through the streets in a cream-coloured French coach, ornamented with cupids and flowers. The leaders of the new nation combined with the aristocracy of the city to give Philadelphia a social life distinguished for its conversation as well as for its gaiety and glitter.

The Philadelphia economy had by this time readjusted from the dislocations of the Revolution and was growing at least as rapidly as before the war. The shipyards were prospering, building vessels of such quality that even Boston, New York city and Baltimore papers advertised ships "built of the best white oak and finished off in the neatest manner on the Philadelphia plan." The U.S. navy yard had been established, building during the 1790s the frigate "United States," on the plan provided by the Philadelphia designer Joshua Humphreys for six sister ships, including the "Constitution." The merchant ships built in Philadelphia yards and sent out by Philadelphia merchants ventured into new quarters of the globe. Thomas Willing was instrumental in organizing the Philadelphia, Boston and New York city venture which in 1784 sent the first American trading ship to China, and thereafter until the middle of the 19th century the city was responsible for one-third of the China trade of the United States. Philadelphia traders, at last outside the British navigation system, found new ports in Europe; coastwise trade also continued to expand. In 1793 the total value of Philadelphia exports was $6,958,736, exceeding those of all New England by $1,717,572 and of New York city by $2,934,370. Behind Philadelphia trade still stood the wealth of the hinterland, which in 1790, for example, sent 150,000 bu. of wheat to the metropolis from the upper Susquehanna country alone.

The Philadelphia golden age of the 1790s was not without a few scars. During the early years of the decade mechanics and artisans aroused by the French Revolution became increasingly noisy in their discontent with the conservative turn of U.S. political events, to the point where some alarmed property owners began to fear new violence. Conservatives and Democrats alike suspended political agitation, however, in the face of the great yellow fever epidemic of 1793, in which perished between 4,000 and 5,000 people, one-tenth of the city's total population.

Meanwhile Philadelphia moved to leadership of the new nation in still another area, finance. Prerevolutionary America had possessed no banks in the modern sense of the term, but from the establishment of the first such institution, the Bank of North America, in 1781, the growth of an American banking system was rapid. The Bank of North America was chartered by the Confederation congress largely at the urging of Robert Morris, its principal purpose being the financing of the Revolution. Its location in the city assured Philadelphia's position as the first financial centre of the United States. State-chartered banks quickly followed in various places and the charter of the Bank of North America was suspended briefly during the 1780s; but the priority of Philadelphia in banking plus its general economic leadership gave the city continued financial pre-eminence. For this reason as well as because Philadelphia was the national capital, the first Bank of the United States was established there in 1791 and remained even after Philadelphia ceased to be the political capital. After the charter of that bank expired in 1811, state-chartered banks reassumed first place in a financial world of which Philadelphia remained the centre. Stephen Girard of Philadelphia emerged as the principal financier of the War of 1812 and when congress chartered a second Bank of the United States in 1816 it was located in Philadelphia. Through the second bank and the activities of Girard, Philadelphia retained financial leadership until the 1830s, despite the fact that by that time economic supremacy in other matters had passed to New York city.

The 19th Century.—By Andrew Jackson's presidency the golden age of Philadelphia had long since ended. The U.S. capital moved to Washington in 1800 and the capital of Pennsylvania already

had departed from Philadelphia in 1799. The removal of the federal capital cast something of a shadow upon Philadelphia's cultural leadership, presently superseded by that of Boston and New York city. Philadelphia culture in the 19th century was to be distinguished by the presence of such notables as the Peales, Gilbert Stuart, Thomas Sully, Henry Inman and Thomas Eakins in painting, William Rush in sculpture, William Strickland and Thomas U. Walter in architecture, and Walt Whitman as well as lesser lights such as Bayard Taylor and S. Weir Mitchell in literature. But the relative position of the city was far below what it had been; except possibly in painting, there was no longer in Philadelphia a community of national cultural leaders, but simply a collection of various individual luminaries.

Commercial ascendancy passed from Philadelphia partly because its port could not match New York city harbour. The approach to Philadelphia by water was far more difficult, the space for berthing of ships was limited and the port was on occasion impeded by ice in winter (the Delaware is fresh water at Philadelphia). The riches of the Philadelphia hinterland as compared with the narrow Hudson valley had more than offset the deficiencies of Philadelphia harbour during the colonial and early republican periods, but in the early 19th century there was opened to New York city a hinterland far richer and vaster than Philadelphia's: the old northwest, the Great Lakes and Ohio river country. Between Philadelphia and this region rose the barrier of the Appalachian mountains; between New York city and the northwest stretched the open avenue of the Hudson and Mohawk valleys. The completion of the Erie canal in 1825 added immeasurably to the already great convenience of that avenue. Promptly after the opening of the canal, the census of 1830 revealed that for the first time the population of New York city exceeded that of Philadelphia. Even earlier, in 1820, Philadelphia's exports had been only about $6,000,000 to New York city's $12,000,000, while Philadelphia imports had stood at $9,000,000 as against $23,000,000 for New York city.

Philadelphia did not yield its population and economic leadership without a contest. The city sought an answer to the Erie canal, a route of its own into the great valley beyond the mountains. Its effort to solve the problem was extraordinary, for the city promoted and helped to finance the completion of the amazing state-owned "Pennsylvania system" west to Pittsburgh. Beginning in 1834, passengers could travel from Philadelphia to Pittsburgh in 4 days, freight in 12–14 days, over a 394-mi. route combining railroads, canals and inclined planes.

Extraordinary, even heroic, as it was, the Pennsylvania system did not serve to recapture Philadelphia's advantage over New York city; the Erie canal was a more convenient freight-handling system. But even a westward transportation system equal to New York city's could not compensate for the inferiority of the Philadelphia port. This fact emerged clearly after the Pennsylvania railroad was completed to Pittsburgh in 1854; it became one of the great railroads of the world but New York city continued increasingly to outdistance Philadelphia in population, wealth and general economic importance.

With its national pre-eminence lost, Philadelphia embarked on a less spectacular career as a regional urban centre, but the city did not cease to be a major one; it remained second in size among U.S. cities until Chicago finally surpassed it in 1890. The agricultural wealth of the immediate hinterland remained and as the 19th century proceeded this area increasingly supplied industrial wealth as well. Philadelphia looked relatively less to its harbour and more to its inland resources to sustain itself. It developed its own manufactures. The textile industry was among the first to rise in the United States as in other nations in the early stages of industrialization, and in that industry Philadelphia was a leader. By 1825 there were 33 cotton and woolen factories in the city and its vicinity, 20 of them alone working 28,750 spindles. Iron foundries and glass works also secured an early prominence. After 1831 Baldwin locomotives and, still later, Stetson hats carried the name of Philadelphia through the 19th-century world. Philadelphia shoes, especially women's shoes, won note throughout the United States. The city became the principal distributing centre for the anthracite coal fields of northeastern Pennsylvania, which after about 1820 began their era of prosperity. The relative loss of emphasis upon the sea did not bring the abandonment of the shipbuilding industry; the William Cramp and Sons Ship and Engine company, founded in 1830, became the principal builders of the U.S. naval vessels during the 19th century and the builders of merchant ships, foreign and domestic, as well.

With industrial growth, the city's population increasingly spilled over the political limits, which had not changed since the first drawing of the town plan. These limits confined the city to an area of two square miles. Beyond that area, much of Philadelphia county was as densely populated as the city itself. There political subdivisions had sprung up haphazardly until the county included 29 such units, variously organized as cities, townships or boroughs; nearly all of them lay immediately adjacent to each other, constituting for all common-sense purposes a single city but frustrating each other through their political independence. In 1854 the Pennsylvania legislature at last acted to remedy this chaos, passing the Consolidation act, which annexed 28 of the 29 subdivisions into Philadelphia.

The city shared in one way or another in most of the principal national events of the 19th century. The influx of Irish and German immigrants to the United States during the mid-19th century called forth in reaction the first major American nativist movement. In Philadelphia, nativism culminated in a series of riots extending through the spring and summer of 1844, during which two Roman Catholic churches were destroyed by fire, seven civilians and two militiamen were killed and many more persons were injured. Earlier the slavery issue had led to antiabolitionist riots, and this issue continued to divide the city during the Civil War. Philadelphia Quakers had a long history of antislavery activity, but on the other hand prewar Philadelphia was a principal banking and mercantile centre for Southern agriculturalists and had many Southern business connections. Some Philadelphians supported the Union war effort only lukewarmly even after Ft. Sumter, but for the most part the city rallied with determination to the Union cause. Philadelphians followed the leadership of Jay Cooke in contributing to war finance, and their Unionism tended to become more pronounced after the Confederate invasion of Pennsylvania in 1863. The Union League of America was an expression of Philadelphia's support for the Union and membership in the league soon became a mark of status in the city.

Philadelphia was the site of the 1876 Centennial exposition commemorating the adoption of the Declaration of Independence. Financed largely by Philadelphia citizens, the exposition opened 180 buildings along the Schuylkill to more than 8,000,000 visitors. The emphasis of the exposition was upon industrial and commercial technology, in which the United States already ranked as a leading nation of the world.

Journalists remarked during the exposition that the political progress of the United States since independence had not matched material progress; the era was that of "Grantism." The same comment applied to Philadelphia. After the Civil War, the Republican party used its record as a war party, its program of friendship with business interests and an astute cultivation of every city precinct to win a stranglehold on Philadelphia politics. Philadelphia and Pennsylvania were in the hands of the machine led first by Sen. Matthew Stanley Quay and then by Sen. Boies Penrose. In the 20th century a local machine led by the brothers George A., Edwin H. and William S. Vare successfully challenged the statewide Penrose machine for control of Philadelphia, but with no change in the quality of city government. Lincoln Steffens not inaccurately described turn-of-the-century Philadelphia in a phrase that has become a byword, "corrupt and contented."

The city remained contented in its corruption partly because the old problem which had led to the Consolidation act of 1854 had emerged again: population had spilled beyond the city's political boundaries. Many civic leaders moved into the suburbs and out of city politics. They worked in the city but did not live in it and they found bad government tolerable. At the same time the Philadelphia machine, like its contemporaries elsewhere, drew many of its votes from the new immigrants who came crowding

into U.S. cities from southern and eastern Europe unprepared for the responsibilities of democratic citizenship. As in other U.S. cities, the new immigrants sought security by forming neighbourhoods along ethnic lines. The long history of many Philadelphia neighbourhoods as independent political entities made for an unusual degree of neighbourhood parochialism, and the forming of ethnic neighbourhoods intensified that tendency.

The 20th Century.—In the 20th century, especially after World War I, the immigrants and their children gradually became less docile voters. Other factors worked also to undermine the power of the city machine, not the least of which was the growth in the 1930s of federal social welfare programs under the New Deal. Providing social security of various sorts in return for votes had been one of the bulwarks of all urban political machines; the federal government removed such welfare measures from local politics. For these reasons and others, by the mid-20th century traditional machine dominance had much decayed.

Furthermore, the decline of machine politics was only one of a complex of changes stirring in Philadelphia in the middle of the 20th century. By that time the phrase "corrupt and contented" was no longer so accurate; a new sense of civic responsibility had arisen. The citizens always had been proud of their city but that pride was becoming difficult to sustain. Rapid but unplanned industrial and population growth had created slums that were among the worst in the world. A real property survey made in 1934 disclosed that of 506,420 dwellings in the city, 19,035 were unfit for occupancy, while another 28,768 were in need of major repairs. About 19,000 houses were without bathing facilities of any kind. Many of the slum dwellings were of the distinctive "bandbox" type, three stories high but only one room wide and deep. Such were depression conditions in the 1930s, but the years during and after World War II scarcely lightened the housing problem. A large influx of Negroes injected racial issues into already serious difficulties and many parts of Philadelphia became overcrowded Negro ghettoes. At the same time Philadelphia suffered from the common problem of all urban centres in the automobile age, an accelerated decay of the central city as population, industry and even commerce moved into the suburbs. The only virtue in all these developments was that they made it impossible for proud citizens to remain contented; they stimulated the new sense of civic responsibility.

Civic Redevelopment.—The Philadelphia Redevelopment authority, established under a state law of 1945, was constituted under a board appointed by the mayor. Its purpose was to eliminate blighted areas and, in co-operation with both public and private enterprise, replace them with socially and economically sound projects. The authority was to make use of federal, state and city funds. Within ten years, by 1955, 19 areas of the city, comprising about 11.5% of the total area and containing more than 20% of the population, had been scheduled for redevelopment. The continuing activities of the redevelopment authority included construction of middle- and low-income housing, the rehabilitation of certain old row houses, the development of new industrial sites, the conversion of blighted areas into improved and enlarged campuses for several of the city's universities, the provision of new parks and playgrounds and projects for automobile parking and street widening. In many of its activities the redevelopment authority co-operated with the Philadelphia Housing authority, a similar agency outside the regular structure of city government, whose purpose was to clear slum areas and to build on slum and open sites safe and sanitary dwellings for low-income families. Meanwhile, private enterprise rebuilt part of downtown Philadelphia into a planned commercial area, Penn Center.

Thus Philadelphia sought to renew its blighted areas and to assure its citizens of adequate housing, and it made substantial progress toward those goals. But social problems spawned during several centuries of unplanned growth could not be remedied in a decade or two; large blighted areas remained in the 1960s and new ones tended to appear as old ones were eliminated. Furthermore, new housing alone could not cope with the fact that much of the city's housing problem was also a problem in race relations. Viewing the growth of an already large Negro minority (about 25% of the population in 1960), city leaders considered experiments which would seek to prevent new housing developments from becoming Negro ghettoes.

Government.—Important to the progress of the various redevelopment programs of the mid-20th century was a newly reorganized city government. From its first incorporation under William Penn, Philadelphia was governed under various charters, all drawn up by the Pennsylvania legislature. After the Revolution, the charters tended to model the structure of municipal government upon the state and federal governments, with a bicameral legislature in the city council, an executive in the mayor and his elected and appointed assistants and a municipal judiciary. This system brought a multiplicity of offices and a diffusion of responsibilities grossly inappropriate to city government. Under the charter of 1885, for example, the bicameral city council grew to a total membership of 145, the largest municipal legislative body in the United States, so large that it tended to strangle its own usefulness. The charter of 1919 remedied this particular problem by creating a unicameral council whose membership ranged from 20 to 22. But the charter of 1919 still failed to meet the full needs of a modern city, especially in that the mayor remained too weak an executive to assure efficient or even honest administration.

Philadelphians came to conclude that what their city required was a charter drawn up by its own inhabitants, who understood their own needs. A fight for such a charter went on sporadically after 1922, when an amendment to the state constitution made possible municipal home rule. In 1951 the efforts of a local Com-

BY COURTESY OF THE PHILADELPHIA CONVENTION AND VISITORS BUREAU

PENN CENTER, HEART OF PHILADELPHIA'S REDEVELOPED BUSINESS DISTRICT

mittee of Fifteen combined with revelations of embezzlements by city officeholders to bring the movement for reform to a climax. In that year a special Philadelphia commission drew up a home rule charter, which was accepted by the voters; it went into effect early in 1952.

Under the 1952 charter, the administration is in the hands of a relatively strong mayor, elected for a four-year term. Executive responsibility is focused upon the mayor, who appoints and removes the principal administrative officers and controls expenditures. Furthermore, the mayor participates in the legislative function by recommending measures to the council, exerting his influence for their passage and exercising a power of veto which can be overridden only by a two-thirds vote of the membership of council. The mayor formulates the city budget, with the council simply voting lump-sum appropriations to each agency. The council consists of 17 members, 10 of them elected from geographic districts and 7 elected at large. While the council's administrative powers are severely limited in order to assure the responsibility of the mayor, its legislative powers are broad; it can legislate on many matters which before 1952 required state legislative action, notably in the fields of public health and municipal salaries.

Most municipal activities are in the hands of 14 departments, which are co-ordinated by the mayor's four principal appointees: (1) the managing director, who supervises the departments of police, fire, streets, water, public health, public welfare, recreation, licenses and inspection, records and public property; (2) the director of finance, who conducts, under the mayor, budgeting, accounting and purchasing, and supervises the departments of collections and procurement; (3) the city representative, who is the city's chief public relations officer and heads the department of commerce, through it holding responsibility for wharf and airport facilities; and (4) the city solicitor, who heads the law department which gives legal advice to city agencies and represents the city in litigation. In addition, there are various independent or semi-independent boards and commissions, such as the civil service commission.

The school district is a governmental unit completely separate from the city government. In addition to the city government and the school board, five "authorities" created for special purposes outside the regular governmental structure operate within the city. These are the Philadelphia Housing authority, the Philadelphia Redevelopment authority, the Philadelphia Parking authority, the Philadelphia Airports Improvement authority and the Delaware River Port authority, the latter an interstate body.

Philadelphia courts are part of the judicial system of Pennsylvania and thus are constitutionally separate from the city government. Their structure is that which is common to all Pennsylvania judicial districts, with the exception that Philadelphia also possesses a municipal court, with limited jurisdiction over specified civil and criminal actions, and 28 magistrates' courts, which have jurisdiction in minor civil and criminal cases and hold preliminary hearings in more serious criminal cases.

An amendment to the state constitution was passed in Nov. 1951, consolidating the Philadelphia city and county governments, with all county agencies becoming city agencies. Subsequently there was a gradual integration of the former county offices into the structure of city government.

The home rule charter and the progress of city-county consolidation did much to give Philadelphia effective government, but they also left many problems unsolved. For example, the problem which the Consolidation act sought to solve in 1854 emerged again in aggravated form. In 1960 there were 625 governmental units in metropolitan Philadelphia on the Pennsylvania side of the Delaware alone. The tendency of this multiplicity of governments was to complicate such issues as police protection, water supply and urban transportation. There was an obvious need for some measure of general metropolitan area government; but there were many obstacles, both constitutional and traditional, in its path.

Industry, Commerce and Transportation.—The leading industries are metals and metal products, textiles, food products and chemical and petroleum products. During the mid-20th century industrial expansion was especially noteworthy in the metals industry, with the establishment at Morrisville on the Delaware of a new plant of the United States Steel corporation intended for the processing of ore from Labrador-Ungava and Venezuela.

Railroads serving Philadelphia and its industries include the Pennsylvania, of which the city is the headquarters, the Reading and the Baltimore and Ohio. Truck and motorcar transportation proceeds from the city over a highway network dominated by the Pennsylvania turnpike to the west and the New Jersey turnpike to the northeast. The Philadelphia International airport brings to the city the services of transcontinental and trans-Atlantic air lines.

Although visitors are likely to remark that in no U.S. seaport is the presence of maritime activity less evident except in the immediate waterfront area, and although the harbour has long since ceased to be the major focus of Philadelphia commerce, the port continues active. The Delaware River Port authority supervises the second largest port in the United States, surpassed only by New York city, and the largest fresh-water port in the world.

The trend in banking in Philadelphia as elsewhere in the latter part of the 20th century was toward consolidation into larger institutions. In 1950 there were 39 commercial and savings banks in the city; in 1960 there were 27.

Education.—The Quakers who founded Philadelphia were not devoted to education with the ardour of the Puritan fathers of New England. They favoured schooling in the rudiments of learning and in practical subjects but were inclined to regard higher learning as a form of worldly ostentation. Therefore they early founded elementary and some secondary schools but they did not hurry to do more. William Penn and his council hired a schoolmaster in 1683 and in 1689 leading Quakers established the Friends' Public school, now the Penn Charter school, which was intended to be open to students of poor families without fee. Not until the mid-18th century, however, was an institution approaching collegiate rank inaugurated. In 1755 various antecedents coalesced to form the College of Philadelphia. By that time the original emphasis on modesty in learning as in living had lost ground among many Philadelphia Friends and in any case the intellectual leadership of the city had passed largely to Anglicans and disciples of the Enlightenment. Once established, the college rose rapidly to prominence among kindred institutions of British America. It was noteworthy among colonial colleges especially for the emphasis upon scientific studies and modern languages which its founders, including Provost William Smith, sought to place beside the traditional preoccupation with the classics. But it had to pass through further vicissitudes during the revolutionary era before it emerged as the University of Pennsylvania.

Meanwhile numerous private and church-related elementary schools and academies had made their appearance, with Germantown academy (1780) and Episcopal academy (1785) notable among the latter. During the late 18th century proposals for state-sponsored public education began to arise but it was not until 1818 that Pennsylvania took a substantial step in that direction by establishing in Philadelphia a school district where pupils might obtain education at public expense. By 1830 more than 34,000 children had received instruction, with girls between 5 and 13 and boys from 6 to 14 eligible for its free services. The Philadelphia school district now maintains public schools through senior high school. The Roman Catholic archdiocese maintains an extensive educational system, including elementary, special and high schools. There are over 40 other private schools.

The University of Pennsylvania, founded in 1740 (*see* PENNSYLVANIA: *Education*), and Temple university, founded in 1884, are the largest institutions of higher learning in Philadelphia. Other institutions in the city include Philadelphia College of Pharmacy and Science (1821); Philadelphia College of Textiles and Science (1884); Jefferson Medical College of Philadelphia (1825); Hahnemann Medical College and Hospital (1848); Women's Medical College of Philadelphia (1850); St. Joseph's, a Roman Catholic college for men (1851); Divinity School of the Protestant Episcopal Church (1862); Lutheran Theological seminary (1864); La Salle college, a Roman Catholic college for men (1863); Chestnut Hill college, Roman Catholic, for women

BY COURTESY OF THE UNIVERSITY OF PENNSYLVANIA

ALFRED NEWTON RICHARDS MEDICAL RESEARCH BUILDING ON THE CAMPUS OF THE UNIVERSITY OF PENNSYLVANIA

(1871); Eastern Baptist Theological seminary, coeducational (1925); Drexel Institute of Technology, a private coeducational institution (1891); and Dropsie college, Jewish coeducational (1907). In the metropolitan area are Haverford (1833), Swarthmore (1869) and Bryn Mawr (1880), colleges Quaker in affiliation or origin, and Villanova, a Roman Catholic university (1842).

On the grounds of Temple university is an interfaith chapel dedicated as a memorial to the four U.S. army chaplains—George L. Fox and Clark V. Poling (Protestants), Alexander D. Goode (Jewish) and John P. Washington (Roman Catholic)—who died together in the sinking of the torpedoed troop transport "Dorchester" (Feb. 3, 1943) after each had given up his own life jacket to another passenger or crew member.

Cultural Activities.—During the 18th century, Philadelphia led the British colonies in the establishment of libraries open to the public. In 1731 Benjamin Franklin and his associates founded the Library Company of Philadelphia, the first subscription library in America. Three other such libraries had been founded when the first public library in the colonies, the Loganian library, based on James Logan's collections, was opened in 1760. By 1792 the Library company had absorbed the other collections. Meanwhile the American Philosophical society had also begun a noteworthy library and the Pennsylvania hospital had established the first medical library in the United States. The 19th century witnessed the founding of the Philadelphia Bar Association Law library (1802), the Philadelphia athenaeum (1814), the German society library (1817), the Mercantile library (1821) and the Philadelphia City institute (1852). In 1891 was chartered the Free Library of Philadelphia, the present municipal library. In 1943 this institution received custody of the Library company and the Loganian library, and in the following year of the Philadelphia City institute and the Mercantile library, thus establishing a unified system. Among the approximately 280 private and special libraries in Philadelphia, that of the University of Pennsylvania is outstanding. The libraries of the Historical Society of Pennsylvania and American Philosophical society are especially rich in documents relating to American history.

Philadelphia was also something of a pioneer among U.S. cities in the establishment of museums; soon after the Revolution Charles Willson Peale, the artist, opened his famous museum in Independence Hall, a hodgepodge collection of stuffed animals, a mastodon skeleton, curious gadgets and portraits of American patriots. Most of the portraits remain in Independence Hall.

Philadelphia has attempted to sustain the artistic tradition begun by Charles Willson Peale and, before him, Benjamin West. There are in the city about 40 art associations, schools, museums and collections, public and private. The Pennsylvania Academy of the Fine Arts, oldest art institution in the United States, dates officially from a charter of 1805, but unofficially from Peale's efforts to organize an art school beginning in 1791. Its schools remain among the most distinguished in the United States. Thomas Eakins was long an instructor, and among those he stimulated were the artists of the Henri group, or the Ash Can school (*see* HENRI, ROBERT). The permanent collection of the academy is rich in examples of the evolution of U.S. art.

The Philadelphia Museum of Art, a huge Greek temple standing on the leveled top of Fairmount, offers collections giving a broad view of the development of art throughout history. It has noteworthy "period" rooms, outstanding special collections such as the Arensburg collection of 20th-century painting and much U.S. and Philadelphia material. Associated with it is the Philadelphia Museum School of Art, founded in 1877–78.

In the promotion of science, the American Philosophical society continues in the path opened by Franklin and his fellow scientific leaders of 18th-century Philadelphia. The Academy of Natural Sciences (1812), the oldest such institution in the United States, has sponsored numerous explorations, including Adm. Robert E. Peary's voyage of 1892 which proved that Greenland is an island. It maintains a museum in its headquarters building. The Franklin institute (1824) emphasizes the promotion of applied science and also maintains a large public museum.

The theatre in colonial Philadelphia, as elsewhere in colonial America, had to surmount obstacles both in public attitudes and in law in order to establish itself. Itinerant performers drew crowds to the outskirts of the city as early as the 1720s, but the usual date given for the establishment of the Philadelphia theatre is 1754, when Lewis Hallam's company arrived from London. Within little more than a decade, in 1766, the Southwark theatre was erected, and the next year occurred the performance of Godfrey's *The Prince of Parthia*, the first American tragedy. Thereupon the Philadelphia theatre entered upon a century of imposing development. The completion of the first Chestnut Street theatre in 1793 was an architectural as well as a theatrical event. The Walnut street theatre, opened in 1809, remains as the oldest existing theatre in the United States. The Arch street theatre (1828) became the most famous of all Philadelphia theatres, associated with Joseph Jefferson and the Drews. Late in the 19th century, however, a theatrical decline set in, as the Philadelphia stage became increasingly a satellite of the New York city stage.

Music in Philadelphia began with the German immigrants; the first recorded recital was given by German mystics, the Hermits of the Wissahickon, who in 1703 played the viol, oboe, kettledrum and trumpet at an ordination service in Old Swedes' church. During the heyday of the colonial city a wider musical interest developed. An Italian music master helped encourage the art; the first public concert was given in 1757; and Francis Hopkinson emerged as the first American composer of any importance. Organized cultivation of music was a product of the 19th century, with the organization of the Harmonic society (1802), the Haydn society (1809), the Cecelia society (1824) and, most important, the Music Fund society (1820), which built its own hall in 1824 and established a school of music there. At this hall the principal performances took place until the opening in 1857 of the Academy of Music, home of the Philadelphia symphony orchestra.

Hospitals.—Philadelphia has been a medical-surgical centre since the 18th century. The Pennsylvania hospital (1751) was the first to be established in the British colonies and it early dis-

tinguished itself especially in the study of mental diseases. The medical school of the University of Pennsylvania (1765) is the oldest in the country. A Philadelphia medical society was organized in 1768 and the College of Physicians and Surgeons was established in 1787. There are more than 40 general hospitals and more than 30 special hospitals and dispensaries within the city.

Parks and Recreation.—The Philadelphia city park system of more than 7,500 ac. (3,035 ha.) includes large and small parks scattered through the city, athletic fields and play areas, maintained by the board of education, and Fairmount park, supervised by a special agency of the city government. It comprises almost 4,000 ac. (1,619 ha.) and extends 10 mi. (16 km.) along the Schuylkill river and Wissahickon creek, including within its boundaries the beautiful Wissahickon and Cresheim valleys, the Philadelphia Zoological gardens, oldest in the United States, Robin Hood Dell for summer concerts, 15 historic mansion houses, 2 surviving buildings of the Centennial exposition, more than 50 sculptural groups and figures and many miles of driveways, avenues, footpaths and bridle paths. Throughout the park system there are varied recreational facilities, including golf, baseball, football, swimming, boating and tennis. A special board of trustees administers Convention hall, which can be used as an indoor sports arena. Independence Hall is now a part of the Independence National Historic site, 18 ac. (7 ha.), administered by the National Park service since 1951. The Old Custom House, a fine example of Greek revival architecture and site of the second Bank of the United States, is also a part of the national park and monument system.

PHILADELPHIANS, a sect of religious mystics, holding a kind of nature pantheism, who flourished in London in the latter part of the 17th century. In 1652 John Pordage (1607–81), rector of Bradfield, Berkshire, gathered together a few followers of Jakob Böhme (*q.v.*), the chief of whom was Jane Lead or Leade (1623–1704). Mrs. Leade had been from girlhood of a mystical temperament and experienced visions which she recorded in a diary entitled *A Fountain of Gardens*, beginning in 1670, in which year the Philadelphian Society for the Advancement of Piety and Divine Philosophy was definitely organized in Bradfield (it later moved to London). In 1693 some of Mrs. Leade's writings were translated into Dutch, and by this means and her acquaintance with Francis Lee, an Oxford scholar who studied medicine at Leiden and became her son-in-law, a connection was opened up with Germany and Holland. In 1703 the Philadelphians drew up their confession, but they made no further progress and after Mrs. Leade's death soon declined, the Dutch branch withdrawing and the English government forbidding the society to meet.

PHILADELPHUS, a genus of deciduous shrubs including the popular garden forms commonly known as mock orange or syringa (the latter is also the generic name of the lilac). *Philadelphus*, comprising about 70 species, belongs to the saxifrage family (Saxifragaceae). The characteristic orange-blossom fragrance of many species is the chief reason for the name mock orange for these plants. They have opposite entire or toothed leaves, the pith being solid, the lateral buds hidden in the leaf axils. The flowers are solitary or arranged in terminal or lateral clusters, the parts in groups of four, the petals mostly white, in some varieties somewhat purplish at the base, and with numerous stamens. The fruit is a capsule with many small seeds.

These decorative and fragrant spring-flowering shrubs are much planted in temperate regions because they grow unusually well in dry soils, endure the trying conditions encountered in city gardens, and are subject to few insect pests and plant diseases. The growth habit is usually upright with arching branches, most of which originate at the base of the plant. Some species are not more than 4 ft. high, others may attain a height of 15 ft.

ROCHE

PHILADELPHUS VIRGINALIS, COMMONLY KNOWN AS MOCK ORANGE

Perhaps the oldest *Philadelphus* in cultivation is the very fragrant common mock orange (*P. coronarius*), a shrub up to 10 ft. high with clusters of creamy-white flowers; its varieties include kinds with golden flowers, double blossoms, and leaves bright yellow in youth. *P. microphyllus*, a smaller shrub, has solitary 1-inch-wide flowers with a pineapple scent. *P. lemoinei*, a hybrid of *P. coronarius* and *P. microphyllus*, has given rise to a number of horticultural varieties with large and fragrant flowers. *P. virginalis*, with semi-double or double blossoms, is useful for forcing. (E. D. Ml.)

PHILAE (Arabic Jazirat Filah), an island of the Nile measuring about 500 by 160 yd., situated at the head of the First Cataract about 2 mi. above the Aswan Dam. Philae is the Greek name; the Egyptian term was P-aaleq, and the Coptic Philak, meaning "the frontier," since it marks the boundary with Nubia. The earliest buildings are those of Nekhtharheb (Nectanebo II), last king of the 30th dynasty (359–341 B.C.), whose temple to Isis, partly destroyed by flooding, was rebuilt by the 2nd and 13th Ptolemies and enjoyed a great reputation and prosperity in Ptolemaic and Roman times. As a reputed burial place of Osiris it was sacred alike to the Egyptians and Ethiopians; and the island of Philae and its neighbour Bigeh (Bijah, ancient Sinan) were regarded as the sources of the Nile and the home of the Nile god. The worship of Osiris and Isis continued there for nearly 200 years after the Edict of Theodosius I in A.D. 378 suppressing the old religion. The priests of Isis obtained great powers unequaled elsewhere in Upper Egypt, probably because they held the gold mines at Wadi Alaki and controlled the terminus of the caravan route at Kubban.

Other temples on Philae include one dedicated to Arsnuphis, with a Coptic Church within; a temple to Imhotep, and one to Hathor; chapels to Osiris, Horus, and Nephthys; the kiosk built by Trajan and dedicated to Isis and Horus; and two Coptic churches. These structures were thoroughly explored and strengthened in the years 1895–96, before being partially flooded by the building of the Aswan Dam. They are now almost entirely submerged, owing to the raising of the dam, except for dry years and for some years in the dry season. (*See* Aswan.) At first it was thought that the flooding would have little effect on the granite temples, but the water damaged the salt-encrusted stones, and by the mid-20th century they were showing considerable signs of weathering and disintegration. (M. V. S.-W.)

PHILANTHROPY, literally "love of mankind," refers to benevolent efforts to promote human welfare and especially to help the handicapped, the sick, and the poor. The term, though it was used by Jeremy Taylor in a sermon about 1650, does not seem to have been commonly employed before the 18th century. It is used interchangeably with the older word "charity," but the latter may also have particular religious connotations (*see* Charity).

Usually, though not always, philanthropy applies to large-scale enterprises aiming at the prevention as well as the relief of human ills (*see* Foundations, Philanthropic). This article traces the origins of philanthropy in personal, religious, and social sanctions to care for members of the family, or kinship group, and to extend hospitality to strangers. It briefly surveys the influence of the teachings of Buddhism, Islam, Judaism, and Christianity and the history of philanthropic institutions up to the time of the 16th-century poor laws, which were a landmark in the

recognition of social (secular and legal) as well as moral and religious obligations to aid the unfortunate (*see* POOR LAW). (*See* also POVERTY.) For the development of modern public and private philanthropic programs *see* CHILD WELFARE; PENSIONS; SOCIAL SECURITY; SOCIAL SERVICE; SOCIAL WELFARE. International Programs are discussed under UNITED NATIONS EDUCATIONAL, SCIENTIFIC AND CULTURAL ORGANIZATION; UNITED NATIONS RELIEF AND REHABILITATION ADMINISTRATION; INTERNATIONAL REFUGEE ORGANIZATION; WORLD HEALTH ORGANIZATION; and FOOD AND AGRICULTURAL ORGANIZATION.

Historically, philanthropy grew out of the obligations of the family, or kinship group, to care for its members and to extend hospitality to strangers. The self-maintaining clan-family (patriarchal extended family) encompassed successive generations and provided a special niche for the elderly, the sick and disabled, and the widowed and orphaned. In cities, however, this form of social organization was sometimes disrupted and other forms of aid became necessary: in Egypt the Pharaoh and his appointed agents gave shelter to the poor and distributed bread and clothing. It was believed that charity and good works would assist the soul in attaining salvation after death.

EARLY GREECE AND ROME

In ancient Greece and Rome the provision of food and shelter for the stranger involved precise rules and a code of conduct resembling the formal courtesies adopted by primitive peoples everywhere toward the tribal guest. Vagrants and beggars were under the patronage of the gods and on that account held to be deserving; later, as evidenced in the *Odyssey* and in Hesiod, they were regarded as nuisances. Begging was a recognized means of self-maintenance and the treatment of beggars a perennial problem.

In early Greek communities, as recorded by Hesiod (8th century B.C.) of Boeotia, customary laws of charity involved duty to one's guest and to one's family, especially to orphans and the aged, and also a reciprocal duty to one's neighbour. Four hundred years later a pupil of Aristotle reported that the Boeotians were well-to-do farmers, practising justice, good faith, and hospitality and giving freely of their substance to needy neighbours and strangers: "for meanness and covetousness are unknown to them." Early Greek examples of philanthropy directed toward communities rather than individuals include that of Cimon of Athens, who gave and laid out parks and gardens; and that of Xenophon, who created an endowed foundation in Scillus to provide food for all on days of festival. One function of feasts was the relief of the poor: beggars carried away extra food in their "wallets," as, later, Roman clients carried away portions of food in baskets (*sportula*) from their patrons' dinners. Throughout Greece inns or resting places for strangers were maintained at or near temples, also initially the centres of medical relief for wayfarers and the poor, and there were brotherhoods in which hospitality was a duty and that supported a kind of common relief fund. These practices continued until the Christian era.

In early Rome, public lands (*ager publicus*) were distributed by the state to citizens without property. As the patrician families acquired more and more of the land, other philanthropies had to be undertaken, and a kind of poor relief in the shape of cheap or free distribution of grain to all citizens was instituted: the *annona civica*. The right to relief was dependent on the right of citizenship; it was hereditary and passed from father to son. It was thus in the nature of a continuous endowed charity affecting the whole population, although later it became necessary to restrict the civic bounty to as few persons as possible.

The *sportula*, referred to previously, represented the home charity of the clan-family and the charity of the patron to his clients. During the empire particularly, leading citizens displayed munificence and benevolence in other ways. Thus in the 1st and 2nd centuries A.D., rich citizens gave freely for education, municipal games, etc., and some endowed religious or charitable institutions. Corporations of craftsmen (*collegia*, forerunners of guilds) were widespread. They embraced artisans and even slaves who contributed regular sums toward the costs of common worship, funerals, care for orphans and widows, and loans to the needy. But under the emperor Severus (A.D. 193) the *collegia* were brought under state control. This marked their decline as benefit societies and their transformation into purely industrial guilds controlled by the municipalities.

The first recorded charitable foundation linked with the Roman "poor" as a class was apparently the *alimentationes* for bringing up poor children, founded probably by Nerva or Trajan about the end of the 1st century A.D. Hospitals in Rome developed from a refuge for sick slaves that existed in republican times on an island in the Tiber. By the 1st century private hospitals or *valetudinaria* for slaves and poor freemen had come into being, and these were followed by the public hospitals of the later empire.

BUDDHISM AND ISLAM

All the great teachers and philosophers who have influenced the history of the East stressed that the well-to-do had duties toward the unfortunate. As a result there are many examples of public philanthropic works, especially provisions for the sick and infirm.

In ancient India philanthropy was promoted by the teachings of the Buddha. Buddhism, a profoundly ethical religion, naturally emphasizes compassion for suffering and the doing of good deeds as one of man's duties and a source of merit. A scriptural writing of Theravada Buddhism, the *Khuddaka Patha*, in a teaching reminiscent of the Sermon on the Mount, counsels, "By charity, goodness, restraint, and self-control man and woman alike can store up a well-hidden treasure—a treasure which cannot be given to others and which robbers cannot steal. A wise man should do good—that is the treasure which will not leave him." Mahayana Buddhism emphasizes the doctrine of the Bodhisattva, the compassionate saviour, and man is urged to follow his example. The *Tathagataguhya Sutra*, describing the qualities of the Bodhisattva, says: "He gives the best food to those who are hungry. He protects those who are afraid. He strives for the healing of those who are sick. He delights the poor with his riches. . . . He shares his riches with those afflicted by poverty. He bears the burdens of those who are tired and weary."

The Buddhist emperor Asoka (*c.* 274–232 B.C.), according to one of his inscriptions, provided medical facilities throughout his realm and caused wells to be dug and trees to be planted for the enjoyment of man and beast. The infirmaries of Buddhist monasteries sometimes took patients from outside, and in Ceylon Buddhist monks studied medicine and visited the sick. In China there were houses of refuge for sick people, isolation hospitals, sick-visiting, nursing, and support of the needy. Craft associations, or guilds, undertook much benevolent and charitable work. Typically, these paid attention not only to the material needs of the sick and infirm but also to their spiritual needs and to the religious proprieties; thus much importance was attached to the fitting burial of deceased members.

Philanthropic works have long been among the glories of Islam. Indeed, one of the five "pillars" or obligatory duties of Islam is the payment of the *zakat* tax (from the root verb *zaka*, "to be pure," which indicates its connotations), which is levied in varying percentages on specified types of property and is distributed to several categories of the needy. In addition to this obligatory alms, the voluntary payment of charities (*sadaqat*) is considered highly meritorious, a witness to the truth of the Muslim's religion. Numerous specific references in the Koran indicate the Prophet's concern for the giving of alms; *e.g.*, "Of their goods take alms, that so thou mightest purify and sanctify them" (ix, 103); "Those who rehearse the Book of God . . . spend (in charity) out of what We have provided for them, secretly and openly" (xxxv, 29).

The early caliphate maintained an elaborate system of assistance to the widows and orphans of its soldiers and colonists. As early as A.D. 707 the first great hospital was founded at Damascus, followed in the last years of the 8th century by one in Baghdad, founded by Harun al-Rashid. In 1283 the Mameluke sultan Qalawun opened the great hospital in Cairo. In it, patients were isolated for study and treatment; there were separate wards for patients suffering from dysentery, fevers, diseases of the eyes, and

bone injuries; and there were galleries for convalescents. A resident staff of men and women was supported by a full organization of storerooms, dispensaries (backed by a herb garden), kitchens, library, lecture rooms, and accommodations for "interns." Famous doctors—including some Christians and Jews—attended the patients and also made domiciliary visits, distributing food and medicines. Qalawun declared that this noble and magnificently endowed foundation was "for kings and servants, amirs and common soldiers, rich and poor, bond or free, men and women alike," and directed that all indigent patients should receive a sum of five pieces of gold on their discharge. Another form of Muslim philanthropy was the founding of universities, some of which, such as Al Azhar (970) in Cairo, are among the oldest in the world.

Medical education in Europe largely sprang from Moorish Spain: the *Altasrif* of the Spanish Muslim physician Abul Kasim includes some surgical notations and has been styled "the common fountain of modern medicine." Moorish foundations in Spain, North Africa, and the Middle East included lazar houses (leprosariums), which had originated in Armenia about A.D. 260.

JUDAISM AND CHRISTIANITY

Jewish ethical thought recognized from the beginning that the poor had rights and that the rich had duties. This was exemplified in injunctions such as that for the remission of debts every 7th, or sabbatical, year and every 50th, or jubilee, year; and in those governing the right of the poor to glean in the fields, and the distribution of largess at weddings and funerals. The Decalogue refers to sabbath rest for the stranger within the gates of Israel (Ex. 20:10); and the Levitical ordinances enjoin love of one's neighbour as oneself and good treatment of the stranger in memory of Israel's sojourn in the land of Egypt (Lev. 19:18 and 19:34).

Ideal and practice were continued in later Jewish history, partly because of the need for solidarity. From the period of the fall of the Jewish state, the charity overseer was part of the recognized institutional system of every community. Numerous voluntary associations existed for the care of the indigent and unfortunate. By the Byzantine period the Jewish charitable inn heralded the appearance of endowed charity: every ghetto had its lodging house for indigent strangers. Alms were collected not only for the poor of the city but on occasion "for the poor of the whole world," as the 12th-century rabbi Maimonides testifies, and it was laid down in the codes that a town without proper charity organization was not a proper place of residence for a self-respecting Jew. It was also expected that he would devote a tithe of his income to philanthropy.

Christian teaching from the beginning inculcated charitable activity as essential to the showing forth of that love that is the fulfilling of the law (Rom. 13:8–10); and many Christians at all periods have found the motive for their philanthropy in Christ's saying: "Truly, I say to you, as you did it to one of the least of these my brethren, you did it to me" (Matt. 25:40). Some, however, with a materialistic view of the rewards and punishments of the afterlife, have seen, in almsgiving especially, a means of "making God their debtor"; and this was particularly obvious in the medieval period.

Early Church Foundations.—In the early years of the Christian Church, the congregational fund was used to succour the poorer members and those who had suffered for their faith; to bury such as lacked means, and to care for their widows and orphans. Later, through administration of charitable funds by the deacons, the churches of Rome and other large towns became well endowed, especially from the time of an edict of the emperor Constantine (A.D. 321) which for the first time authorized the willing of property to the church. Although the edict was temporarily withdrawn (by Valentinian in 379) because of legacy-hunting by the clergy, by 529 it had become legal to give property for "churches, hostels, poorhouses, infant and orphan homes, homes for the aged, and for any such community." A share of an estate left to "Christ our Lord" was held to be payable to the nearest church "to become the alimony of the poor." Legacies "to the poor" of a district were payable to its church. Such gifts were treated as given to pious uses, as "alms," and were free from taxation. Thus grew up the system of endowed charities, for the most part in relation to the church or administered by its officers.

Medieval Philanthropy.—Out of these privileges emerged a system of philanthropy shaped by three factors: the position of the bishop, the eleemosynary nature of church funds, and the need for some responsible charitable organization within an expanding church. Originally all income of the church from alms and gifts was paid into one fund, intended primarily for the poor. Before the reign of Constantine very few church buildings had been erected and the church was in large measure a charitable society. When the need for funds for building was recognized, a fourfold division of offerings was made: (1) for the bishop; (2) for the clergy; (3) for the poor; and (4) for church buildings. (Traces of this arrangement survive in the organization of funds in the Church of England.) Thus a separate fund for almsgiving, supervised by the bishop, was created and up to the time of Charlemagne (*c.* 750–800) philanthropy was mainly parochial; measures to aid the poor consisted principally of assistance in the home. But during the wars and confusions of the 9th and 10th centuries, almsgiving tended to be more and more obscured by the rise of the feudal system, which changed the obligation of individuals to their church and to the poor of their parish into an obligation to their feudal masters, to whom they were bound by fealty. By the same process, the officially recognized clients of the church came to consist of the gradually decreasing number of free poor and those who were tenants of church land. Under these circumstances, the revenues of property and charity for the poor all too often enriched private or ecclesiastical purses. Sometimes, however, they passed to the newly founded monasteries, which became institutional centres of relief, providing through an almonry to the aged, infirm, lame, and blind (who were visited in their homes), and for travelers and the ever-present mendicants. Sometimes the almonry contained rooms for the sick. These were the forerunners of the hospitals, which by the 12th century were commonly created out of the rich foundation endowments of the monasteries (*e.g.*, a grant of land was made by Henry I of England to the abbey of Abingdon "to the use of the alms of the said abbey"). From the 11th century, the number of hospitals greatly increased. About 750 existed in England by 1540. The continent of Europe showed similar development and European explorers helped introduce hospitals to the New World (*e.g.*, the Hospital of Jesus of Nazareth, founded by Cortés in Mexico City in 1524). (*See* also HOSPITAL: *History of Hospitals.*)

Almshouses, too, were founded; for example, four in Canterbury, two of which were endowed by Lanfranc in 1084, one for poor, infirm, lame, and blind men and women, and one (outside the town) for the victims of leprosy; *i.e.*, all sufferers from disfiguring diseases. These institutions were attached to and administered by a priory and endowed with tithes. The hospital in its modern sense was but slowly created. Thus the earliest great hospitals of London, St. Bartholomew's (1123) and St. Thomas's (1200), were part almshouses and part shelters for poor, diseased, and disabled in-patients; they also cared for orphan children. St. Thomas's, founded by Peter, bishop of Winchester, had a master and brothers and lay sisters, and provided 40 beds for the sick, poor, or aged. (Guy's Hospital—the last general hospital to be endowed by a single person—was founded in 1724 to relieve the overcrowding at St. Thomas's.) There were many hospital orders (including the "Hospitaller" Knights of St. John of Jerusalem, who have operated hospitals for the poor from the 12th century to the present day), and the friars of the newly founded Franciscan order went about tending the sick and distressed wherever they might be found.

Often almshouses and schools were created out of a common endowment and in a single complex of buildings, as was the "hospital" and school of Archbishop Whitgift (1596). Both (though the school has been rebuilt) still survive as one foundation.

Religious institutions were not the only centres of organized philanthropy; municipal authorities, too, took an increasing share in promoting the welfare of their inhabitants. This happened first of course in the countries where town life was early important: in Italy, for example, in the 9th century. By the 13th

century many municipalities maintained *tables des pauvres* such as that at Ypres (Flanders; 12th century) for local residents and pilgrims. The merchant and craft guilds, which rose to importance in the later Middle Ages, also conducted secular charitable activities. Richer citizens willed lands and funds to their guilds or municipalities for the maintenance of almshouses, the education of children, and the support of widows and unmarried daughters —usually with preference for the families of other guild members or those born in the city. Endowments were made to finance apprenticeships and loans to young men starting in trade, and there were benefactions for the support of poor scholars at the universities.

A curious mixture of nonendowed public and private philanthropic action is found in the medieval method of dealing with disasters such as fires. Before the Reformation, these had usually been the occasion of church collections: but from that time royal letters patent, known as charity "briefs," authorized collections in specified parishes or districts or in all the parishes of a county. Any surpluses were applied to the building of hospitals, bridges, causeways, etc.; *e.g.*, to record a single instance, to repair the Cobb (pier) at Lyme Regis, Dorset. Boroughs also were left land and funds from which to maintain roads, fords, embankments, and bridges or, as in Scotland, for "the general good of the community."

Decline of Medieval System.—The system of monastic and church-door poor relief had begun to break down a long time before the Reformation. The methods of charity practised by the monasteries had been indiscriminate, property of the hospices had often been diverted from its intended use, and the hospitality of monasteries or hospices had frequently served the rich rather than the poor. Against this popes and church councils fulminated in vain. The Council of Vienne (1311), after condemning corrupt administrators of leprosariums, hospices, and hospitals, had forbidden the transformation of charitable foundations into clerical benefices. The edict was renewed by the Council of Trent. In many countries, consequently, attempts were made to transfer the administration of foundations to secular control. Thus in France from the time of Louis XII a series of ordinances sought to reorganize the administration of philanthropic institutions and to take them out of the control of religious bodies. The same tendencies were found in England, and the suppression of the monasteries under Henry VIII and Edward VI did not destroy a system of relief that had previously been working effectively, but rendered more apparent the amount of pauperism that existed.

These were the circumstances from which evolved the policy of public support through compulsory taxation to relieve at least extreme poverty through the enactment of poor laws. (*See* Poor Law and Poor Law: *United States.*)

PHILARET (1553?–1633), patriarch of Moscow who from 1619 ruled Russia in harmony with his son Tsar Michael, was known in his secular life as Fedor Nikitich Romanov, being the eldest son of the boyar Nikita Romanovich. During the reign of his cousin Fedor I (1584–98), he distinguished himself both as a soldier and as a diplomat. On the death of the childless tsar, he was the popular candidate for the vacant throne; but he acquiesced in the election of Boris Godunov (*q.v.*), who compelled him, three years later, to take monastic vows under the name of Philaret. Philaret was confined to the Antoniev Monastery, near Kholmogory, but when the first False Dimitri overthrew the Godunovs he released Philaret and made him metropolitan of Rostov (1606). In 1609 Philaret fell into the hands of the second False Dimitri, who named him, apparently against his will, patriarch of all Russia—though in fact his jurisdiction was limited. In September 1610 Philaret was sent by the Muscovite boyars to King Sigismund III of Poland to negotiate for the accession of the latter's son Wladyslaw to the throne of Russia. The king's intransigence caused these negotiations to break down, and Philaret was eventually arrested and sent to Poland, where he was kept in confinement (1611–19). After the election of his son Michael Romanov as tsar of Russia (1613) and a long-delayed exchange of prisoners, Philaret returned to Moscow and, on July 4 (new style; June 24, old style), 1619, was enthroned patriarch. Father and son then shared the sovereignty of the realm as co-regents.

Philaret replenished the treasury by a more rational system of assessing and collecting the taxes. His most important domestic measure was the chaining of the peasantry to the soil, a measure directed against the ever-increasing migration of the serfs to the steppes, where they became freebooters instead of taxpayers. The taxation of the tsar's *sluzhilye lyudi*, or military tenants, was a first step toward the proportional taxation of the privileged classes. Philaret moreover formed the nucleus of the Patriarchal Library and commanded that every archbishop should establish a seminary for the clergy, himself setting the example. He also reorganized the Muscovite Army with the help of foreign officers. His death, in Moscow, on Oct. 11 (N.S.; 1, O.S.), 1633, put an end to the attack on Poland that had been launched in 1632, since it deprived Russia's still weak executive of its strongest prop.

See R. N. Bain, *The First Romanovs* (1905).

PHILARET (Vasili Mikhailovich Drozdov) (1782–1867), metropolitan of Moscow, whose strong personality, broad learning, and acute perception of the needs and demands of contemporary church life made him one of the most important and influential prelates and theologians of the 19th-century Russian Orthodox Church. He was born at Kolomna near Moscow on Dec. 26 (old style), 1782, the son of a priest. He completed the usual training as priest in 1803 at the seminary of St. Sergius' Monastery of the Trinity, and immediately entered on a brilliant career as teacher in theological seminaries and academies, first in Moscow and from 1809 in St. Petersburg, his subjects including Greek, Hebrew, philosophy, poetry, biblical hermeneutics, biblical history, church history and Christian archaeology, canon law, and dogmatics. On the advice of his patron, the famous metropolitan of Moscow Platon Levshin, Drozdov became a monk (1808) and speedily rose in ecclesiastical rank and office. As rector of the St. Petersburg theological academy he was a member of many committees on the reform and improvement of theological studies in Russia. From 1817 vicar bishop of St. Petersburg and from 1819 archbishop of Tver (now Kalinin), he was a member of the Holy Synod until the end of his life, although from 1843 to 1855 he was in disgrace with the high procurator N. A. Protasov and could make his influence felt only indirectly. On July 2 (O.S.), 1821, he became archbishop of Moscow and on Aug. 22 (O.S.), 1826, metropolitan. Philaret died in Moscow on Nov. 19 (O.S.), 1867.

As metropolitan, Philaret was widely active in church politics, interesting himself particularly in reunion with members of the church in east Poland and in establishing a connection with the Old Believers. His *Mnenia i otzivi* (1905; "Views and Comments") dealt with all the theological, ecclesiastical, and political questions of his time, and their influence can hardly be overestimated. He worked eagerly for the introduction of a modern Russian translation of the Church Slavonic Bible and from 1814 to 1858 he fought a hard, and finally successful, battle on its behalf, associated as he was with the fate of the Russian Bible Society, of which he was a member until its dissolution. His most important literary work apart from his sermons is his catechism, which he first published in 1823 and of which he was obliged to publish three versions revised in accordance with the reigning theological opinions of the Holy Synod, that is of the tsarist government. It became the official 19th-century Russian Orthodox catechism.

See Philaret's *Catechism* (Eng. trans.) in P. Schaff, *The Creeds of Christendom*, 2nd ed., vol. ii (1877). *See* also D. Jugie, "Philarète Drozdov," in A. Vacant, *Dictionnaire de théologie catholique*, vol. xii (1933). (F. v. L.)

PHILATELY (STAMP COLLECTING) is the hobby of collecting and studying postage stamps. The first postage stamps for prepayment of letter postage were issued in England in 1840. Almost everything connected with them began at that date, including the vocabulary needed for the hobby of stamp collecting and even the name stamp itself. For the history of posts and postal systems, *see* POSTAL SERVICES.

The term philately was coined in 1865 by a Frenchman, M. Herpin, who invented it from the Greek *philos* "love," *a* "negative," *telein* "to tax"; since the postage stamp was evidence of a letter's coming free of charge to the recipient, the postage stamp rendered it untaxed. The term caught the popular fancy much more than the word timbromania (Fr. *timbre* "stamp") previously used, and became the accepted word to describe stamp collecting and the study of postage stamps.

I. HISTORY

In 1835 Rowland Hill (*q.v.*) began to study the tax situation in England, there having been a surplus of revenue. He noted that while reduction of tax rates sometimes brought a reduction of net revenue, the reduction of the tax on coffee by one-half had produced a net increase in revenue of one-half. Furthermore, he determined that postal revenues were falling despite increased rates, while a reduction in postal rates in France had increased the net revenue.

Further inquiry revealed that since most letters went through post unpaid, to be collected on delivery, many of these were refused and had to be returned, often to be unclaimed or refused on return, thus necessitating records at every step of the two-way trip, as well as double portage for no revenue. Most illuminating of all was the discovery that the cost of transport per letter was frequently less for a long journey—from London to Glasgow, for example—than for a short one—such as London to Kent—for the long haul went with a greater number of letters than the short local trip. Hill therefore proposed a radical change: that letters be carried any distance within Great Britain and Ireland for a fixed rate, which he suggested be a penny for each one-half ounce, and that all postage be prepaid. Wrappers and envelopes with the stamp denoting prepayment were to be sold at all post offices, and for those who wished to use their own stationery he proposed "a bit of paper just large enough to bear the stamp" (he meant the imprint of the post office hand stamp), "and covered at the back with a glutinous wash, which might, by applying a little moisture, attach to the back of the letter, so as to avoid the necessity for redirecting it."

Hill's pamphlet, *Post Office Reform*, was issued in January 1837 for private circulation. Parliament investigated, and the postmaster general Lord Lichfield reported that of all the wild and visionary schemes he had ever heard or read of, it was the most extraordinary. A second edition of the book, for public circulation, had its effect. The public response was loud and strong, the treasury reduced rates to a uniform 4*d.* per ½ oz. basis, and in 1839 reduced it to Hill's proposed 1*d.* per ½ oz. regardless of distance, effective Jan. 10, 1840.

Hill was asked by the treasury to work out the details. In 1839 he entrusted the design of the envelope and wrapper to William Mulready (*q.v.*). To create the "bit of paper," he held a public competition, and more than 2,600 essays were entered. Meanwhile, Hill had heard of a new process of steel engraving, in which he became interested. When the prizes (four of £100 each) were awarded, the "label" with the glutinous wash on the back was finally produced by the new, revolutionary Perkins process for reproducing steel engravings.

Jacob Perkins, a native of Massachusetts, was an inventor of mechanical devices. In 1819, having invented the D-roller copperplate press, an engine lathe for engraving copper and steel plates, and the triple transfer process of reproducing steel engravings together with the machines to carry it out, he was persuaded to travel to England to interest the Bank of England in the process for producing its notes. The British minister to the United States extended the invitation, and though the Bank of England finally decided to proceed with a process then being installed, a grant, reported to be £5,000, was made to Perkins and his partners. Meanwhile, he secured the business of many other banks, for prior to 1844 almost every British bank issued its own notes.

In brief, the essence of the process is: a soft-steel die is engraved with the original intaglio of the proposed finished engraving. This master die is then hardened and a soft-steel roller is pressed against it in a transfer press and rolled back and forth until a transfer in relief is obtained on the roller. A second, third or fourth relief or even more, likewise can be obtained on the transfer roll, each of them in relief; *i.e.*, the lines that are cut into the original die and that will retain the ink to make the print of the engraving are in relief on the transfer roll. The roll is hardened, in turn. The last stage is to impress the transfer roll against the plate from which the printing is to be done, once more in the transfer press. The relief lines become intaglio lines on the printing plate, exact reproductions of the original die, reproduced as often as wished.

To the inventor's firm of Perkins, Bacon and Petch (later Perkins, Bacon and Co.), Sir Henry Cole, on behalf of Hill, suggested in December 1839 the possibility of securing the contract for the proposed labels.

For Hill's label, the background chosen was an engine-turned lathework that had been used often as a background of bank notes. To use this on the stamp, a die block was impressed with the proper amount of the geometric pattern from the transfer roll. (This same transfer roll was later used to make the background for the Cape of Good Hope triangular stamps of 1853, the St. Vincent one-crown stamps of 1880 and the New Zealand George V series of 1915. It is now in the possession of the Royal Philatelic Society.) The overall size and the space for the portrait of the queen were carefully marked. The pattern was transferred to a roll, and the space for the queen's head and the unused portion were burnished clean. The roll was then entered on a new die block. The portrait chosen was that engraved by W. Wyon of the royal mint for the medal struck commemorating the queen's first visit to the city of London in 1837. Henry Corbould made the drawing, and the engraving was made directly on the die by Charles and Frederick Heath. The first die was not used and a second was made. Above the head was a panel with the word "Postage," the upper corners were embellished with a cross pattée; below was a panel with "One Penny" or "Two Pence"; in the lower corners were initials. Hill was afraid of counterfeiting, and for this reason the initials were used.

Each plate (11 were used for the one-penny value and two for the two-pence the first year) contained 240 stamps; each horizontal row of 12 was therefore valued at as many shillings as the single stamp was worth pence. There were 20 rows, each full sheet being worth in pounds what each stamp was valued in pence. The lower right-hand corner of the stamps was lettered "A" for the first vertical row, "B" for the second and so up to "L" for the 12th; the lower left corner was similarly lettered "A" for the first horizontal row, "B" for the second and so to "T" for the 20th. It was thought that any counterfeiter would use only one or two combinations, and any very frequent recurrence of these would apprise the postal clerks of the attempt.

Neither the envelopes and wrappers nor the stamps were ready

in January. Hand stamps were used to mark the letters "paid" until May 6, 1840. On May 1, both stamps and envelopes, including wrappers, were ready—the one-penny black, the two-pence blue—and were put on sale. They were not valid for postage until May 6. It was Hill's thought that the envelopes and wrappers would be in demand, and adhesive stamps would be merely for the exceptional user. But in fact, it was the stamps that were in demand, and the printers worked night and day to keep the offices supplied, while the original supply of the envelopes and wrappers was never exhausted in the year they were available for postage.

In the latter part of 1885 James Chalmers, whose father had been a printer in Dundee, advanced the proposition that Hill had stolen the idea for the adhesive postage stamp from the elder Chalmers. Both the principals were dead, but an unpleasant controversy arose that was scotched by Chalmers' own evidence, which gave the date of his father's suggestion as after Hill's (quoted above) had been read into evidence before a parliamentary committee. However, from time to time, copies of Chalmers' vitriolic pamphlets come into the hands of newcomers to philately and provide another tempest in a teapot.

Although Hill's estimate of the loss of revenue was greatly surpassed by the facts, there was never any serious question of reverting to the old system. Prepaid postage, and with it the adhesive label that later became the postage stamp, had become accepted.

In 1843 the empire of Brazil issued three values of postage stamps, becoming the second government to use them. These stamps did not contain the portrait of the emperor, but large figures of value on a background of engine-turning, and are popularly known as bull's-eyes. In the same year two Swiss cantons, Zürich and Geneva, issued stamps. That of Geneva was a double stamp: a half paid the postage within one commune, the whole paid it within the canton.

The first adhesive stamp in the United States was issued in 1842 by the semiofficial City Despatch Post of New York City for local carrier delivery. In 1845 several postmasters in the United States issued stamps to facilitate prepayment of letters—New York City issued a 5-cent value; St. Louis issued 5- and 10-cent stamps (later adding 20-cent); and the postmaster at New Haven, Conn., issued a 5-cent envelope.

In the succeeding two years, more postmasters issued similar local labels all with the tacit consent of the postmaster general, since the postmasters were charged with each letter they forwarded "paid" and the issuing of the stamps was merely their own method of bookkeeping.

In 1847 the United States issued stamps of 5- and 10-cent value and the "postmaster's provisionals" were abandoned. Prepayment became obligatory in 1856.

In 1845 the Swiss canton of Basel issued a stamp. In 1847 the British colony of Mauritius issued two values made locally that have become two of the philatelist's most sought-after rarities. In 1848 the Bermuda postmaster issued a provisional similar in purpose to those issued by the U.S. offices between 1845 and 1847. France and Belgium issued their first stamps in 1849, as did Bavaria. In 1850 Austria, Hanover, Prussia, Saxony and Schleswig-Holstein in central Europe, Spain and the three British colonies of New South Wales, Victoria and British Guiana all issued stamps. So did the Swiss federation, replacing the cantonal issue of previous years, for these stamps were valid in all cantons.

The first British stamps bore no country name, being intended only for internal use. Subsequent issues of Great Britain have likewise been content to bear the legend "Postage" without any designation of the country of issue. The first Brazilian issue was also without a name. The Swiss stamps, seeking to avoid giving offense to German-, French- or Italian-speaking Swiss, were likewise without a country name; subsequent issues avoided argument by carrying the Latin name "Helvetia," or later "Confoederatio Helvetica."

After 1850 the remaining countries of the world began to issue stamps, more being added each year. Some countries began with local issues for the larger cities. Others plunged into national production. Following World Wars I and II numerous new countries and subdivisions issued stamps, while others ceased to exist as stamp-issuing entities.

II. STAMP MANUFACTURE

Although the first stamps, those of Great Britain, were made by intaglio printing, not all stamps are so made. Five basic processes of printing are used in making stamps: (1) the engraved or intaglio process, in which the lines to be reproduced are incised into the surface of the plate and inked, while the surface is wiped clean;

1. Production.—The first stamps were made by private contractors under governmental supervision. Great Britain still contracts with private companies for supplies of stamps. The United States began by contracting for both postage and revenue stamps but, after the Civil War, the Treasury Department began printing its own tax stamps at the Bureau of Engraving and Printing. In 1885 this bureau bid on the postage stamps, but lost to a private concern, the American Bank Note Company. In 1894 the bureau was low bidder; thereafter it produced the postage stamps as well as the revenue stamps, banknotes, currency and bonds.

France also began with a private contractor, but after 28 years transferred the production of stamps to the national mint. Many countries have followed the lead of Great Britain and entrusted their stamps to private concerns—Perkins, Bacon and Co., which produced the first British stamps, also produced the original issues for many other countries. For Chile, for example, the company printed the first issue in sheets of the same dimension and layout as the first British issue, which made bookkeeping rather difficult for the Chileans, who use a decimal currency. Most countries with decimal coinage use sheets of 100.

2. Paper and Watermarks.—Philatelists are deeply conscious of the kind of paper used for stamps. Chief item in papermaking for stamps is the watermark (*q.v.*), a sign or symbol made in the paper as it is manufactured. On paper to be used in printing stamps, watermarks may be spaced so as to fall on each particular stamp, or to run through the sheet in a recurring pattern or to fall with one quarter on each stamp, a block making a full pattern. Typical watermarks are the small crown that appears on each of the 1840 stamps of Great Britain or the "crown and C A" (crown agents) on many colonial stamps; the "USPS" used by the United States between 1895 and 1915, a letter or part of one letter falling on each stamp; or the wavy lines used by Bavaria for early issues, which fell on each stamp and in the margins as well.

Basically, paper is wove or laid. Wove paper is made on a woven screen, and either presents no appearance other than general opacity when held to the light, or it dimly resembles a tiny network, as a woven screen greatly reduced. If the screen is strengthened with heavier wires evenly spaced in one direction, it becomes a laid paper, with these lay-lines showing. If these are exceptionally heavy, it is called batonné paper, and if the heavy batons are placed perpendicular to lay-lines it is laid batonné. A thin onionskin paper sometimes used for stamps is called *pelure* paper.

Paper in which coloured fibres are used, presenting a gray or mottled appearance, is termed granite paper. Silk paper has tiny threads of coloured silk worked into it, and silk-thread paper has one or two very noticeable silk threads laid lengthwise or across it, falling on each stamp. (*See* also PAPER MANUFACTURE.)

3. Gum.—The glue applied to the back of the stamp, which is moistened and thereby made to adhere to the envelope, wrapper, etc., is referred to as gum. Different kinds of gum may be distinguished by colour, opacity, streaks, etc. Stamps may be ungummed. Usually gum is applied to the sheet of stamps before the perforation process is performed.

4. Perforation.—The first stamps were printed on a sheet of paper with no provision for separation one from the other. This required use of a knife or scissors to secure individual stamps. Such stamps are known to collectors as imperforate. In 1847 an Irish engineer, Henry Archer, offered a machine to provide stamps with separations. A toothed wheel cut a series of scallops between the stamps, permitting easy tearing of the sheet. Experiments were made by the British Post Office, and in 1848 the machine was put in service. However, the wheel used to cut the scallops soon became blunted; it also damaged the work table. A new set of wheels with lancet-shaped knives fared little better. In 1849 Archer introduced a machine that punched tiny holes between the rows of stamps. Such sheets as were not ruined in experimenting were sold in the regular course of business by the post offices. In 1854 the machine was so far perfected that thereafter all British stamps were perforated.

Philatelists differentiate between these various methods of separating stamps. The first method, which cuts the paper between the stamps but does not remove any of it, is called rouletting; it is further differentiated by the pattern of the cutting: serpentine, scalloped (or *en arc*), saw-toothed (or *en scie*), straight-line (or *en ligne*), etc. When small portions of the paper are removed, it is termed perforated. These, with imperforate, make up the three main classes of separation of stamps.

Philatelists further differentiate stamps by their perforations. To many, though not all, collectors, a difference in the number of perforations creates a separate, collectible variety. To obviate differences caused by slight variations in the dimensions of stamps, philatelists measure the number of perforations in 20 mm. Thus, "perf. 12" means that there are 12 holes counted in 20 mm., and so on. Roulettes are similarly counted.

III. STAMP COLLECTING

No one can say with certainty when stamp collecting began, but clearly it was subsequent to May 1, 1840, when the first postage

stamps were put on sale. The earliest reference to it is in an advertisement in the *Times* of London in 1841:

A young lady, being desirous of covering her dressing-room with cancelled postage stamps, has been so far encouraged in her wish by private friends as to have succeeded in collecting 16,000. These, however, being insufficient, she will be greatly obliged if any good-natured person who may have these (otherwise useless) little articles at their disposal, would assist her in her whimsical project. Address to E. D., Mr. Butt's, Glover, Leadenhall Street; or Mr. Marshall's, Jeweller, Hackney.

That this mania for accumulating, if not collecting, was rather widespread within the year is evidenced by this paragraph in *Punch*, 1842:

A new mania has bitten the industriously idle ladies of England. To enable a wager to be gained, they have been indefatigable in their endeavours to collect penny stamps; in fact they betray more anxiety to treasure Queen's heads than Harry the Eighth did to get rid of them!

Accumulation led to collecting, in all probability, though there is no evidence of just how or where it started.

1. Catalogues.—From the practically simultaneous appearance of catalogues in the 1860s, it seems clear that collecting was spontaneous and not confined to any one region. Great Britain, France, Germany, Belgium and the United States apparently had active collectors prior to 1862. In the British magazine *Notes and Queries* of June 23, 1860, appears a letter from a schoolmaster recounting that one of his pupils had a collection of 300 or 400 different stamps, and that "Sir Rowland Hill had told him at that time there might be 500 varieties on the whole." He suggests that a list of stamps would be useful and asks if there is any shop in London where stamps are sold and that has a list available. The identical idea must have been surging in other lands. In 1861 Oscar Berger-Levrault, in Strasbourg, issued his list of stamps, *Timbres-Poste*, by lithography from manuscript. In Paris, Alfred Potiquet published a *Catalogue des timbres-poste crées dans les divers états du globe*. The acceptance of the lists must have been immediate, for Berger-Levrault issued a second edition later in the year. In January 1862, J. B. Moens of Brussels, Belg., issued his *Manuel du collectionneur*. In England, Frederick Booty, J. E. Gray and Mount Brown all issued catalogues in 1862. A pirated edition of the last, listing 1,200 varieties, was issued by A. C. Kline in Philadelphia. Brown issued two more editions of his catalogue, the third (1866) listing 2,400 varieties, inclusive of what is now termed postal stationery or envelopes, wrappers and letter sheets, as well as many local issues.

The standard modern catalogues exclude this latter material, and yet the total number of listings, including minor varieties, reaches more than 200,000.

E. Stanley Gibbons issued in 1863 a catalogue that continues to be one of the major catalogues of Great Britain. The standard in France is by Yvert and Tellier; in Germany it is Michel's catalogue, in Switzerland Zumstein's. The Scott catalogue (originating in 1863) and the Minkus catalogue (begun in 1954) are standard works for the United States. Each of the above catalogues stresses information about the country in which it is issued, either as part of the main volume or in a separate specialized edition which may include postal stationery. Also, because of the sheer bulk of printed matter needed to catalogue over 200,000 philatelic items, the major catalogues tend to be published in two or three volumes; shortened versions for beginners and general collectors are produced by both Gibbons and Scott.

Many stamps are issued for postal charges other than letter carrying (*see* below), and some of the major catalogues list these also. Revenue and telegraph stamps, issued to prepay telegrams in certain countries, also are collectible and may be listed in modern catalogues.

2. Albums.—The first stamp albums were issued in 1862. Justin Lallier originated both the French and the English editions, in Paris. He rapidly increased his albums, to accommodate new stamps as they were issued, and for several years held first place among collectors for the completeness and arrangement of his books. In the latter part of the decade (1867) he began to add information about stamp collecting and bibliographies.

3. Special Stamps.—Airmail stamps are issued especially for letters to be carried by air. Italy issued the first of these for the first government-sponsored experimental flight in 1917; the first regular issue was that of the United States the following year. Almost every country has issued them since, with the exception of Great Britain and its colonies, though in these countries certain values of the regular postal issues are of denominations primarily for airmail use. Special delivery, registry, insured and acknowledgment-of-receipt stamps are for payment of the special fees levied for these services. Late fee stamps are sometimes issued to pay the extra postage for letters mailed after the closing of special mails.

Official stamps are issued for the use of governmental departments. Formerly widely used, they are now largely supplanted by printed franks.

Semipostal stamps are sold at a premium over their letter-carrying value, the overage going to some officially recognized charity. Postage due stamps indicate the amount a letter lacks of full payment of the charges, which is collected on delivery. Newspaper and parcel post stamps are for the special duties indicated.

Commemorative stamps are regular postage stamps issued to honour some event, activity or person of national importance. The first stamps of this kind were issued by New South Wales in 1888, on the 100th anniversary of the founding of the colony. Argentina (1892) and the United States (1893) issued stamps commemorating the 400th anniversary of the discovery of America. In 1897 Great Britain and Canada signalized the diamond jubilee of Queen Victoria's coronation. Thereafter, the practice became common.

4. Specialization.—When Mount Brown's catalogue listed 2,400 stamps (1866), a modest collection of 2,000 varieties would contain more than 80% of all stamps. A similar proportion in the 1960s would necessitate 150,000 varieties. Because of the sheer bulk, not to mention the prohibitive expense, of such a general collection, most collectors turn to more or less limited fields. For example, they may collect only the stamps of one country, or of one continent or of one period. Others specialize in collections of certain kinds of stamps; some collect only one issue and study it thoroughly, others may collect only revenue stamps or postal stationery. Those interested purely in stamp designs may collect art or religion on stamps, or flowers, fish, bridges, etc.; this sort of collecting is called topical or thematic.

The collection of postal markings, both on stamped and pre-stamp covers, is a form of specialization; collecting of precanceled stamps is another. Meters (machines that print a postal frank on the envelope) have given rise to yet another specialized form. Telegraph stamps are also collected by some specialists.

Plating.—The collecting of one issue or even of one stamp of an early issue, may necessitate some of the deepest philatelic study. The early stamps, especially the engraved ones, were often retouched after transfer, so that each stamp on each plate has minute identifiable characteristics. For instance, it is possible to identify each of the 2,640 specimens of the Great Britain one-penny of 1840, and this is easy, compared with other issues, because the plate position is located by the check letters in the corners. It is also possible to identify most of the 2,600 varieties of the 3-cent U.S. stamps of 1851. This has led to "plating" or reconstruction of the original sheet, which in turn has led to many discoveries of the ways in which sheets were laid out and manufactured.

BY COURTESY OF HELEN K. ZIRKLE
FIRST U.S. CHRISTMAS SEAL, 1907

Christmas Seals.—Christmas seals were invented by a Danish postal clerk, Einar Holbøll, in 1903, as a source of revenue for an antituberculosis society. They were used on packets and letters sent at Christmas, and sold for a small sum, the money going to the society. The use spread to many other countries, where they are issued each year. While they have no franking power, they are widely used and often collected.

Government Philatelic Agencies.—Specialization in 20th-century stamps has been helped by establishment of governmental philatelic agencies to sell fine-quality stamps to collectors. The United States opened the first of these in 1921, and the success

was soon so apparent that similar agencies were established by many European countries. The U.S.S.R. made traffic in stamps a government monopoly and Germany followed suit when the Nazi Party came into power. In 1942 the U.S. placed revenue stamps on sale at a special agency for collectors.

The forms of specialization are limitless, and the ingenuity of collectors leads to the constant discovery of new and individual methods.

5. Famous Collections.—Many famous collections of the past have been dispersed and absorbed by others. One of the most famous of all times was the collection of Philippe la Renotiere von Ferrari, an Austrian subject resident in Paris. During World War I he fled to Switzerland, where he died in 1917. His property was seized by the French government, and his collection, which he had formed during 40 years, was sold at auction, realizing more than 26,000,000 fr. (£400,000 or $2,000,000 at the rates of exchange of the day).

Arthur Hind's collection, which included the Duveen collection of Mauritius and the Griebert collection of Spain and which was sold in 1933–34 after his death, brought a gross return of nearly $1,000,000. In addition, the unique 1-cent British Guiana magenta of 1856 was sold by private negotiation for a price reputed to be more than $50,000, the highest price ever recorded for a single stamp.

BRITISH GUIANA, "ONE-PENNY MAGENTA." THE MOST VALUABLE STAMP IN THE WORLD. IT WAS ISSUED IN 1856

The outstanding collection in Europe in the 1960s was the private collection of Queen Elizabeth II. Principally formed by King George V, who was a famed philatelist, it is especially rich in British and colonial issues.

Of the several famous collections in the United States, one of the most bizarre was formed by Col. E. H. R. Green; it stressed unusual materials, such as quantities of the "blue paper" issues of the U.S., the only position blocks of the 24-cent airmail with inverted centre (U.S., 1918) and a number of sheets of the imperforate 5-cent carmine error (U.S., 1915). Other noted collections were those of Sol Newbury (Chicago), Alfred Lichtenstein and Theodore Steinway (New York). Alfred H. Caspary's stamps were sold in the late 1950s in New York City for $2,895,146, the largest sum realized by any stamp collection to that time.

The Thomas K. Tapling collection, bequeathed to the British Museum, may well be the finest in public hands. The Smithsonian Institution collection at Washington, D.C., stresses U.S. stamps. The postal museums of many European capitals have outstanding collections, such as those at Berlin, at The Hague and at Stockholm; the last received the Hans Lagerlof (New York) collection.

IV. PHILATELIC SCHOLARSHIP

1. Societies.—Clubs or societies of collectors are to be found in most cities of the world, with national and international societies tending to bind them together. The American Philatelic Society, founded in 1886, had about 13,000 members in the 1960s; the Society of Philatelic Americans (1894) had about 6,000. The Royal Philatelic Society of London was founded in 1869 and became "royal" in 1906. The Junior Philatelic Society of London was founded in 1899. The Collectors Club of New York stands preeminently for philatelic research, as does the Royal Philatelic Society. Many countries have national philatelic organizations with research groups.

Because of the quantity of philatelic material, added to each year by the issuance of about 3,000 new stamps, with the resultant tendency to specialization, specialist societies have sprung up, notably since 1945. Many of these issue bulletins. Particularly noteworthy are the specialty clubs dealing with the philately of France and colonies, Germany, Italy and colonies, Korea, Lithuania, Luxembourg, Japan, Switzerland, airmails, postal history, postal stationery, U.S. bureau issues, and others too numerous to list.

2. Congresses.—The Philatelic Congress of Great Britain celebrated its 50th anniversary in 1959 and the American Philatelic Congress celebrated its 25th the same year. The "congress" idea fosters philatelic research by the publication of articles annually in book form, with annual conventions at which these articles are discussed and the material upon which they are based is studied. The first (Congress Internationale des Timbrophiles) congress was held in Paris, June 26, 1878. After 1945, there was an increase in the number of congresses held in various countries.

3. Exhibitions.—One of the most important activities of stamp clubs is the holding of exhibitions from time to time. National and regional societies hold annual exhibitions, offering valuable awards in competition. International exhibitions are held in the United States at approximately ten-year intervals. Other countries arrange to honour philatelic or national events at the appropriate date with similar world-wide celebrations.

4. Literature.—Perhaps no hobby has been so prolific of literature as philately. The standard catalogues (*see* above) issued annually are generally minor encyclopaedias of the hobby, but there are and usually have been journals in every language.

It is difficult to list accurately monthly or weekly publications, since many are short-lived. The first one of record that was specifically devoted to philately was the *British Monthly Intelligence;* appearing first in October 1862, it lasted only three issues. In December 1862 appeared the *British Monthly Advertiser,* which appeared in January 1863 as the *Stamp Collector's Review;* it lasted nearly two years. Moen's (Brussels) published the *Timbre-Poste* for many years, starting in 1863, in which year the German *Magazin für Briefmarken-Sammler* began. In 1874 John K. Tiffany published *The Philatelical Library,* a catalogue of philatelic literature in his extensive private library in St. Louis, Mo. This collection of books he afterward sold to the earl of Crawford, who combined it with his own extensive holdings and bequeathed all to the British Museum.

Among the journals founded in the 19th century and still extant are *Mekeel's Weekly Stamp News* (founded 1892) and the *American Philatelist* (published by the American Philatelic Society, founded 1887, but with two lapses since), in the U.S.; the *London Philatelist* (published by the Royal Philatelic Society); and *Echoes de la Timbrologie,* in France.

UNITED STATES, AIRMAIL, 1918; ONLY ONE SHEET OF 100 STAMPS WITH CENTRE INVERTED (PLANE UPSIDE DOWN) REACHED THE PUBLIC

There have been many books on stamp collecting, especially in specialized fields. Since these appeal to a limited public, they are issued in small editions and few remain long in print.

5. Libraries.—In the United States the library of the Collectors Club of New York is outstanding. The Philatelic Library of Los Angeles, the Eugene Klein Collection in the Philadelphia Free Library and that of the Philatelic Research Society (Oakland, Calif.) also are noteworthy. Many public libraries have growing sections devoted to philately and are usually expected to have at least the standard catalogues. In England the library of the Royal Philatelic Society has been kept up-to-date consistently, and in other European countries where there are postal museums, libraries are apt to be an important adjunct. Probably the best private philatelic library is that of George T. Turner of Washington, D.C.

6. Some Philatelic Terms.—Philatelists, like other hobbyists, use words with special meanings pertinent to their collecting. Some have been coined, others are words from current usage twisted to specific connotations. Many words in the philatelic vocabulary have been internationalized from the French.

Bisect.—These are stamps that have been cut in half or into smaller bits to serve as postage; *e.g.,* the 3-cent of the 1869 U.S. issue was bisected (trisected would be a better term, but philatelists continue to use bisect) to permit the mailing of a number of forms that called for only two cents' postage. Such bisects are usually collected only when on the original envelope or mailing

piece, and then with a cancellation identifying them with the letter. Some bisects also have been overprinted with the new fractional value; in such case they bear their own proof of bona fide and do not need the supporting evidence of the letter.

Block.—A block consists of four or more stamps with the horizontal and vertical separations untouched. Thus, a block of four stamps can only be arranged two wide by two deep.

Booklets.—These are blocks of stamps, sometimes all of the same denomination, sometimes of different denominations, arranged between covers, usually with interleaving to prevent sticking. Size and value of booklets is determined by the country of issue.

BY COURTESY OF HELEN K. ZIRKLE

SWEDEN, PAIR OF VERTICALLY PERFORATED COIL STAMPS, 1954

Coil Stamps.—These are stamps issued in long strips—(usually 500) for use in mailing or vending machines. Some countries, notably Sweden, prefer coils for post office sale in place of sheets as they are easier to store. The stamps are usually imperforate on top and bottom (or the two sides) and perforate between the stamps. If imperforate top and bottom, they come from horizontal coils; if imperforate on the two sides, from vertical coils.

Cover.—A cover is the outer wrapping of a piece of mail: the envelope or outer side of a folded sealed letter or the wrapper of a packet. A stamp is "tied to cover" when the cancellation or other postal marking falls partly on the stamp and partly on the cover.

Double Impression.—This occurs where the sheet of paper was put through the press twice, the second imprint shifting slightly from the first one.

Double Transfer.—In engraved stamps this occurs where the impression on the printing plate, either through shifting in the transfer press or an attempt to re-enter and deepen the impression, has caused portions of the entry to have double lines.

Grill or Grille.—This is the impression of a knurled roller on a stamp to break the fibres of the paper so the canceling ink will soak in and prevent washing to reuse.

Hinge.—In arranging a collection, stamps are not pasted directly on the album page but secured there by hinges, small rectangles of paper gummed on one side and folded. The gum is a special kind that allows the hinge to be peeled off with minimum damage to the stamp and its original gum. One gummed section is fastened to the stamp, the fold at the top of the stamp; the other is fastened to the page. Thus the stamp may be lifted at will for study of the back.

Inverted Centres.—These occur only when two or more plates are used to make a stamp. Occasionally a sheet will be reversed when passing through the second press, and the centre will be inverted in relation to the frame; actually the centre may have been printed first, in which case it is an inverted frame.

Miniature Sheet.—This term has two meanings. (1) A form of collecting in which stamps from the corners, sides, top, bottom and at least one from the centre are put together to show every possible variety the sheet possesses—nine stamps from a U.S. sheet of 100 would give this effect. (2) More commonly the term is applied to little sheets of 25, 10 or fewer stamps issued as souvenirs of an occasion or a national event. These are also known as souvenir sheets.

Mint.—This is the condition of a stamp as it comes from the post office, with its original gum undamaged and without blemish on its face. A stamp that has lost its gum but is otherwise unblemished is spoken of as "unused—no gum," save in rare instances when there was originally no gum, in which case it is still mint.

Overprint or Surcharge.—Either of these terms is used to refer to a stamp that has been printed over, to change one or several of the original qualifications. The trend is to use the word overprint, to avoid connotations that have become attached to the word surcharge. Stamps are often overprinted to change the value, usually because there is a shortage of a needed denomination and a surplus of another. Stamps are also overprinted to change the country, as stamps of one nation used in the territory of another in war or after cession. Another overprint is applied to change the use of stamps; a revenue stamp, for example, may be overprinted for postal duty. Stamps that have been withdrawn have been overprinted to make them valid again.

Plate Numbers.—These are often put on the margins of plates, and thus are printed on the sheets, to identify the plate. Sometimes, as with many issues of Great Britain, they are worked into the design and appear on every stamp.

Postal Markings.—These are the cancellations, postmarks and other hand or machine stampings applied by the post office to the letter or piece of mail.

Precancel.—Precanceled stamps are a particular form of overprint, a cancellation applied before sale to the user. Only those with special permits are allowed to use precanceled stamps, and these must be employed according to strict regulations. They are intended to save unnecessary labour by the post office clerks, and are usually used for large mailings of identical pieces or for newspapers or periodicals.

Reissues.—These, not to be confused with reprints, are made by governments, hence are often called government reprints; frequently they are rarer and more valuable than the original issues.

Remainders.—Remainders are stamps left in the hands of governments after they have been demonetized. Sometimes these remainders are sold in bulk and accordingly depress the value of unused stamps.

Reprints.—These are stamps printed from the original plates after the stamps are no longer valid for postage. The only reason for doing this is to sell the stamps to collectors, and reprinted stamps are accordingly generally deprecated by philatelists. A few governments have been guilty of this practice, and some of them have been persuaded to turn the plates over to private parties. The most notable cases were those of certain Central and South American governments which, in the 1890s, entered contracts with the Hamilton Bank Note Company, of New York, by which the company furnished a complete series of stamps each year, and after the stamps had been demonetized, was permitted to sell the remainders and such other stamps as it wished to make from the plates. These issues, called Seebecks after the president of the company, have suffered accordingly. Certain African countries made similar contracts more recently.

PRECANCELED U.S. STAMP

Misprints Reprinted.—In 1935 a Greek postage stamp was overprinted for use as a postal tax stamp and on a few the overprint was found inverted. Though the error occurred unintentionally, the Greek government had many more made to avoid speculation. This is an illustration of what a government may do although most are happy to have the philatelist enjoy the fruits of his discoveries (notably Canada when a small number of the St. Lawrence Seaway 5-cent of 1959 was discovered with inverted centre). On Oct. 23, 1962, a 4-cent bicoloured, two-process stamp was issued by the United States, in the usual quantity of 120,000,000 for commemorative stamps, to honour the late Dag Hammarskjöld, secretary-general of the United Nations. At least two panes of 100 of these stamps with the yellow colour inverted slipped past the inspectors inadvertently, one being found by a collector in New Jersey, the other in Ohio. When this reached the attention of the Postmaster General he ordered printed another 2,000,000 of them (later increased to a total of 10,000,000) on the theory that every collector should have one if he wished. Instead of pleasing philatelists this new policy angered them almost unanimously as it took from their hobby the element of fame and benefit from a possible discovery, always a stimulating factor.

Se-tenant Stamps.—These are two or more stamps unsevered from each other in which one or more of the stamps differ from the other. Sometimes two denominations of stamps are printed in one sheet; a pair of stamps of the different denominations would be described as a se-tenant pair.

Tete-Beche.—Occasionally plates have been made with one stamp entered upside down. Such a stamp is said to be tete-beche, and can only be identified when se-tenant with one or more of the normal stamps.

Indexes and Handbooks: John Boynton Kaiser, "Bibliography: the Basis of Philatelic Research," *19th American Philatelic Congress Book* (1953); John Freehafer and Helen K. Zirkle, "Literature: Philatelic Handbooks, Including a List of Libraries in Which They May Be Found," *22nd American Philatelic Congress Book* (1956). *American Philatelist,* the American Philatelic Society's monthly, prints a quarterly index of current philatelic publications from all over the world. For the specialist, it is recommended that each find out what is available by writing to his nearest philatelic library, and that each study the complete file of publications issued by the specialty group in his chosen field. (M. HA.; H. K. Z.)

PHILEMON (*c.* 363–*c.* 264 B.C.), poet of the Athenian New Comedy, an elder contemporary and successful rival of Menander, whom posterity preferred to him. Born probably in Syracuse, by 328 he was producing plays in Athens, where he eventually became a citizen; he also worked in Alexandria for a time. About 60 titles from his 97 comedies are known; they survive in Greek fragments (perhaps including quotations from his son, Philemon the Younger), and in Latin adaptations by Plautus (*Mercator, Mostellaria, Trinummus* and possibly other plays). His characteristics include neatly contrived plots, vivid description and frequent moralizing in a style which lacks Menander's grace.

Webster, *Studies in Later Greek Comedy* (1953). (E. W. HY.)

PHILEMON, EPISTLE TO, one of the Epistles of St. Paul in the New Testament. Though coming in the canon next before the Epistle to the Hebrews, it clearly belongs with the Epistle to the Colossians and among the "captivity epistles" of St. Paul. Both Philemon and Colossians allude to Onesimus; both send greetings from Timothy, Epaphras, Mark, Aristarchus, Luke, and Demas; in both the writer is a prisoner. For the date, therefore, and the imprisonment in question, *see* COLOSSIANS, EPISTLE TO THE.

The primary purpose of this epistle is to persuade one Philemon to forgive and receive back his slave Onesimus, who had apparently (though this is not explicitly stated) absconded, perhaps with money or goods, for which the apostle undertakes to compensate Philemon. St. Paul would have liked to keep Onesimus with him, to wait upon him in his imprisonment as Philemon's representative, but he would do nothing without Philemon's consent, and, indeed, it was illegal to harbour a runaway slave. At the very least, however, he confidently asks Philemon to welcome him kindly: does not Philemon owe his very self to the apostle? This seems to mean that St. Paul had brought Philemon to Christ, a service he appears also to have done for the slave. The epistle includes a brief but weighty reference to the meaning of Christian love and faith, and shows that Paul was expecting release shortly. It is important for showing how Christianity, though accepting slavery as a matter of course, was revolutionizing the relation between master and slave; Onesimus, sent back to his owner, is expected to be beloved by him, both as a man and as a Christian. Considering the severe penalties that might have been inflicted, this is remarkable.

Philemon (with Apphia, his wife, and Archippus, perhaps their son) is, like Onesimus (Col. 4:9), a member of the group of Christians in the Lycus Valley (in Asia Minor) and probably resident at Colossae. The letter, not strictly a private one, is addressed to Philemon's house-church. The Epistle to Philemon appears in two 2nd-century canons, that of Marcion and the Muratorian, though its lack of doctrinal importance as well as its brevity (25 verses only) threw it afterward into some disfavour among certain circles of the church. *See* also BIBLE; PAUL, SAINT.

BIBLIOGRAPHY.—For editions, commentaries and translations *see* those quoted in bibliography to COLOSSIANS, EPISTLE TO THE, and the Eng. trans., with commentary by M. R. Vincent (1897), in *International Critical Commentary* and the commentaries in the *Interpreter's Bible* (1955) by J. Knox, in the *Torch Bible Commentaries* (1960) by A. R. C. Leaney, and in the *Tyndale New Testament Commentaries* (1960) by H. M. Carson. *See* also E. R. Goodenough, "Paul and Onesimus," *Harvard Theological Review,* 22:181–183 (1929); E. J. Goodspeed, *The Meaning of Ephesians* (1933); P. N. Harrison, "Onesimus and Philemon," *Anglican Theological Review,* 32:268–294 (1950); T. Preiss, *Life in Christ* (1954); W. L. Westermann, *The Slave Systems of Greek and Roman Antiquity* (1955); J. Knox, *Philemon Among the Letters of Paul,* 2nd ed. (1959). (C. F. D. M.)

PHILEMON AND BAUCIS, in Ovid's *Metamorphoses,* were a pious Phrygian couple who hospitably received Zeus and Hermes when their richer neighbours turned away the gods, who were disguised as wayfarers. As a reward, they were saved from a flood that drowned the rest of the country; their cottage was turned into a temple, and at their own request they became priest and priestess of it. Long after, they ended their lives at the same moment, being turned into trees. Similar stories are given in the *Märchen* ("fairy tales") of the Grimm brothers.

PHILES, MANUEL (13th/14th century), of Ephesus, was a Byzantine court poet in the manner of Theodore Prodromus. He lived in Constantinople under Michael VIII Palaeologus and Andronicus I and II, was acquainted with the chief persons of his day, and traveled widely. His poems, mostly in iambic trimeters, include verses on church festivals, works of art, and animals, as well as dialogues and occasional pieces. Their literary quality is not high, but they have historical and social interest.

BIBLIOGRAPHY.—*Manuelis Philae carmina,* ed. by E. Miller, 2 vol. (1855–57); *Manuelis Philae carmina inedita,* ed. by A. Martini (1900); animal poems ed. by F. S. Lehrs and F. Dübner, *Poetae bucolici et didactici* (1846). *See* also K. Krumbacher, *Geschichte der byzantinischen Litteratur,* 2nd ed. (1897); G. Moravcsik, *Byzantinoturcica,* 2nd ed., vol. 1 (1958).

PHILETAS OF COS (*c.* 330–*c.* 275 B.C.), Greek poet and grammarian, is rightly regarded as the founder of the Alexandrian school of poetry. He was tutor to Ptolemy II and taught Zenodotus, Hermesianax and Theocritus. The titles of five of his poems or collections of poems have survived, the most important being apparently the *Demeter,* an elegy narrating Demeter's wanderings. Though he wrote at least one poem in hexameters Philetas' chief fame was as an elegist. His lady love was Bittis (or Battis) and Hermesianax states that the Coans put up a statue of him singing her charms. Among the Romans Propertius and Ovid mention him as their model. Philetas also compiled a lexicon of *Miscellaneous Glosses* (*Miscellanea*) comprising a collection of rare words from Homer, the Greek dialects and other sources.

See A. A. Day, *The Origins of Latin Love-Elegy,* pp. 14–19 (1938). (E. A. B.)

PHILIP, SAINT, THE APOSTLE, one of the Twelve, so mentioned in the apostle lists, always as the first of the second group of four names (Mark 3:18; Matt. 10:3; Luke 6:14; Acts 1:13). According to John 1:43–51 he came from Bethsaida, answered Christ's call, and was instrumental in Nathanael's call. He had a part in the multiplication of the loaves and fishes (John 6:5–7), and with Andrew acted as a go-between for the Greeks who wanted to see Jesus (John 12:21–22). In John 14:8–9 he asked Jesus to reveal the Father, and received the answer, "Have I been with you so long, and yet you do not know me, Philip? He who has seen me has seen the Father." Nothing more is known about him from the New Testament. In later legends he was often confused with Philip the "evangelist," one of the seven deacons of the early church (Acts 6:5). His apostolate was supposed to have been in the territory of Scythia. He died at Hierapolis, according to one tradition, of natural causes, but according to another, of crucifixion. In medieval art his symbol was loaves (dependent on John 6:7) or a tall cross. His feast day in the Western Church (together with that of St. James the Less) is now May 11. In the Eastern Church it is Nov. 14. *See* also APOSTLE. (J. A. FI.)

PHILIP, SAINT, THE EVANGELIST, is mentioned in Acts 6:5, as one of "the seven" chosen to superintend certain secular business of the Jerusalem church, in consequence of dissension between the Aramaic-speaking and Greek-speaking disciples. Luke in mentioning the common meals appears to want his readers to connect these officials with the later diaconate, but among the Hellenistic

Jews they seem to have been originally parallel to the Twelve among the Hebraists. Philip's was a ministry of the word. He went to Samaria and preached with much success, Simon Magus being one of his converts (Acts 8:9–13). He afterward instructed and baptized the Ethiopian eunuch on the road from Jerusalem to Gaza. His missionary journey ended at Caesarea (Acts 8), where he entertained Paul and his companions on their last journey to Jerusalem (Acts 21:8). His feast day is June 6. (W. K. L. C.)

PHILIP THE ARABIAN (MARCUS JULIUS PHILIPPUS), Roman emperor A.D. 244–249, came of a distinguished equestrian family of Arab descent. He was praetorian prefect when the emperor Gordian III was killed in a mutiny, with or without Philip's connivance. Philip succeeded him, ended the Persian war, and undertook a series of campaigns against the Goths and other tribes on the Danube, returning to Rome to celebrate in 248 the 1,000th anniversary of the foundation of the city. He faced a series of revolts by provincial army commanders, the last of whom, Decius, killed and succeeded him in the autumn of 249. His wife was named Otacilia Severa. Christian writers of the 4th and later centuries regarded him as a Christian, or at least as a patron of the Christians.

PHILIP I (1052–1108), king of France, was the elder son of Henry I of France by his second wife, Anne of Kiev. Crowned at Reims on May 23, 1059, he became the sole king on his father's death (Aug. 4, 1060). His minority, during which Baldwin V, count of Flanders, was regent for him, ended in 1066.

Philip was badly misjudged by contemporary chroniclers, who resented his spoliation of churches and disapproved of his personal life. He in fact increased the royal domain, maintained order in it, and held his own against his powerful vassals, especially by exploiting their quarrels among themselves. As the price of his neutrality in the struggle between the brothers Fulk le Réchin and Geoffrey the Bearded for the heritage of Anjou, Philip obtained Château-Landon and the Gâtinais from Fulk (*c.* 1068), thus securing a territorial link between the county of Sens and the other lands of the royal domain around Paris, Melun and Orléans. He likewise took advantage of the dynastic conflict in Flanders after Baldwin VI's death (1070). He was engaged from 1076 in intermittent hostilities against the kings of England: first against William I, who as duke of Normandy (*q.v.*) had more territory in France than the king his suzerain; then against William II, whose brother, Robert Curthose, was more acceptable to Philip as his vassal in Normandy.

About 1072 Philip had married Bertha, sister of Count Dirk V of Holland. By her he had two children who survived infancy: namely his son, Louis VI (*q.v.*) of France, who was associated with Philip as "king-designate" in the later years of the reign; and a daughter, Constance, married first, in 1097, to Hugh I of Champagne, secondly, in 1106 (after the annulment of her first marriage in 1104), to Bohemund I of Antioch. On May 15, 1092, however, at Tours, Philip abducted Fulk le Réchin's wife, Bertrada de Montfort (*c.* 1070–*c.* 1117). He next demanded the annulment of his marriage with Bertha and of Fulk's with Bertrada; some French bishops took a complaisant attitude; and before the end of October the king and Bertrada went through a form of marriage. Ivo (*q.v.*) of Chartres and other bishops strongly objected to these proceedings; and in 1094, when Philip, on Bertha's death, organized a council at Reims to ratify his designs, Pope Urban II's legate, Hugh of Die, convened a countercouncil at Autun and excommunicated Philip. Urban himself, who had hitherto only protested, excommunicated Philip at the Council of Clermont in 1095. Having promised to renounce Bertrada, Philip was absolved at the Council of Nîmes in 1096; but he soon resumed his relations with her, and in April 1097 his lands were put under an interdict. Absolved again (1098), he relapsed again and was excommunicated by legates of the new pope, Paschal II, at the Council of Poitiers (1100). Finally, in 1104, on his promising to abstain from carnal intercourse with Bertrada and to see her only in the presence of "nonsuspect" persons, Philip was reconciled with the church by the councils of Beaugency and of Paris; and thenceforward Paschal II turned a blind eye to his conduct with Bertrada, who continued to style herself queen. Philip's children by Bertrada were Philip, count of Mantes from 1104; Florus, married to the heiress of Nangis; and Cecilia, married first to Tancred, regent of Antioch, secondly to Pons, count of Tripoli.

Philip I died on July 29 or 30, 1108, probably at Melun.

See A. Fliche, *Le Règne de Philippe Ier, roi de France* (1912).

(M. PAC.)

PHILIP II AUGUSTUS (1165–1223), king of France, with his father, from 1179 and sole king from 1180, was born in Paris on Aug. 21, 1165, the son of Louis VII of France and Adela of Champagne. He was crowned at Reims on Nov. 1, 1179, so as to be associated as king with his father, who had fallen mortally ill. His uncles of the house of Champagne, namely Henry I, count of Champagne, Guillaume, archbishop of Reims, and Thibaut V, count of Blois and Chartres, hoped to control France through the youthful king. To escape from their tutelage, Philip on April 28, 1180, married Isabella, daughter of Baldwin V of Hainaut and niece, through her mother Margaret, of the count of Flanders, Philip of Alsace, who promised Arras, Saint-Omer, Aire and Hesdin —in other words the lands later known as Artois—for her dowry. The Flemings' dreams of power were in turn frustrated by the king who had even less intention of being dominated by Flanders than by Champagne. When the Plantagenet Henry II (*q.v.*) of England arrived in Normandy, perhaps with the intention of responding to an appeal by the house of Champagne, Philip II entered into negotiations with him and, at Gisors on June 28, 1180, renewed the understanding which Louis VII had reached with him in 1177. The house of Champagne was thus politically isolated, and Philip II was already making all decisions for himself and acting as he saw fit when his father died, on Sept. 18, 1180, leaving him sole king in name as well as in fact.

The disappointed count of Flanders soon allied himself with the Champagne faction, and there followed a serious revolt against the king. By the Peace of Boves, however, in July 1185 (confirmed by the Treaty of Gisors in May 1186), the king and the count of Flanders composed their differences, which had been chiefly over the succession to the heritage of Vermandois: the disputed territory was partitioned, Amienois and numerous other places passing to the king, the remainder, with the countship of Vermandois proper, being left provisionally to Philip of Alsace. The king was thenceforward free to turn against Henry II of England.

The Struggle Against the Plantagenets.—Henry's continental possessions, the so-called Angevin Empire—Normandy, Maine, Anjou, and Touraine, with Aquitaine in the hands of his son, the future Richard I (*q.v.*) of England, and with Brittany ruled by another son, Geoffrey (d. 1186)—were a constant menace to the French royal domain. There were also long-standing disputes over the Vexin (*see* NORMANDY), Berry, and Auvergne; Henry's promise that Richard should marry Philip's sister Alice remained unfulfilled; and a new quarrel arose in 1187 over the wardship of the new duke of Brittany, Geoffrey's posthumous son Arthur I.

Philip II launched an attack on Berry in summer 1187, but made the truce of Châteauroux with Henry in June. This truce, which left Issoudun in his hands and also granted him Fréteval in Vendômois, was for two years, but Philip found grounds for resuming hostilities in summer 1188. The estrangement between Henry and Richard was ably exploited by him: Richard did homage to him voluntarily at Bonmoulins in November 1188; and finally, by the Treaty of Azay-le-Rideau or of Colombières (July 4, 1189), Henry was forced to renew his own homage, to confirm the cession of Issoudun, with Graçay also, to Philip and to renounce his claim to suzerainty over Auvergne. Henry died two days later.

Richard, who succeeded Henry as king of England, had already undertaken to go on crusade against Saladin in the Holy Land. Philip now did likewise. Before his departure, he made the so-called Testament of 1190 for the government of his kingdom in his absence. On his way to Palestine he met Richard in Sicily, where they promptly found themselves at variance, though they made their Treaty of Messina (March 1191). Arriving in Palestine they conducted the siege of Acre, but Philip soon fell ill and made this his pretext for returning to France. In fact he was bent on settling the succession to Flanders (Philip of Alsace had just

died on the crusade) while Richard was still absent. By the end of 1191, Philip II was back in France.

In spite of promises made in the Holy Land, Philip at once prepared to attack the Plantagenet possessions in France. Informed of this, Richard also left the crusade, but he was taken prisoner on his way back by the duke of Austria, Leopold V of Babenberg. Philip brought everything into play to prolong his rival's captivity, but Richard was at last set free (1194) and went to war against Philip. The French king suffered a number of defeats (from that at Fréteval in July 1194 to that at Courcelles in September 1198) in a series of campaigns punctuated by negotiations. Luckily for Philip, Richard was killed in April 1199.

Richard's brother John (*q.v.*) was by no means so formidable a fighter. Moreover, his right to Richard's whole succession could be contested by Arthur of Brittany, whose father had been senior to John. To secure the succession, therefore, John came to terms with Philip: by the Treaty of Le Goulet (May 22, 1200), in return for Philip's recognition of him as Richard's heir, he ceded Évreux and the Vexin Normand to Philip; agreed that Issoudun and Graçay should be the dowry of his niece Blanche of Castile, who was to marry the future Louis VIII (Philip's son by Isabella of Hainaut); and renounced any claim to suzerainty over Berry and Auvergne. Shortly afterward, however, John entered into conflict with the house of Lusignan and other Poitevin barons, who appealed to Philip as overlord. Summoned to appear before the royal court as a vassal of the French crown, John did not present himself. Consequently Philip in April 1202 pronounced John's French fiefs forfeit and undertook to carry out the sentence himself. He invaded Normandy, overran the northeast and laid siege to Arques, while Arthur of Brittany campaigned against John's supporters in Poitou; but John, marching south from Maine, captured Arthur at Mirebeau (Aug. 1). Philip in fury abandoned the siege of Arques and marched southwestward to Tours, ravaging John's territory on his way before returning to Paris. Guillaume des Roches, the powerful seneschal of Anjou, who had lately taken John's side, came to terms with Philip in March 1203.

Resuming operations against Normandy, Philip occupied the towns around the great fortress of Château-Gaillard, to which he laid siege in September 1203, having overruled Pope Innocent III's attempts to mediate. John, who is supposed to have murdered Arthur of Brittany in April, retired to England in December, and Château-Gaillard fell to Philip in March 1204. Then Rouen, the Norman capital, surrendered in June, after 40 days' resistance.

After his conquest of Normandy, Philip subdued Maine, Touraine, Anjou, and most of Poitou with less difficulty (1204–05), though the castles of Loches and Chinon held out for a year. He sought to secure his conquests by lavishing privileges on the towns and on the religious houses, but otherwise left the local barons in power. Unrest, however, was endemic in Poitou, and in June 1206 John landed at La Rochelle. After a campaign in the south, he turned north toward the Loire. At Thouars in October 1206 he and Philip made a two-year truce, leaving John in possession of the reconquered Poitevin lands. Next year, however, Philip invaded Poitou again; and after a further campaign in 1208 only the south and part of the west of Poitou remained loyal to John (with Saintonge, some of the Aquitanian hinterland, and Gascony).

Philip next hoped to exploit the dispute between John and Pope Innocent III. When Innocent was threatening to declare John unfit to reign (1212), plans were made for a French landing in England and for the accession of Philip's son Louis to the English throne; but these plans had to be dropped when John made his submission to the pope (1213). John on the other hand threw himself into schemes for revenge and formed a coalition against France: the Holy Roman emperor Otto IV, the count of Flanders (Ferrand or Ferdinand of Portugal), and the count of Boulogne (Raynald or Renaud of Dammartin) were to invade the Capetian territory from the northeast while John attacked from the west, with the help of his Poitevin barons. John landed at La Rochelle in February 1214 and advanced into Anjou, but was put to flight by Louis at La Roche-aux-Moines on July 2; and his confederates were completely defeated by Philip in the decisive Battle of Bouvines (*q.v.*) on July 27. The Anglo-Angevin power in France and the coalition had been broken in one month. Meanwhile, in 1213, Philip had transferred Brittany to his cousin, Peter (*q.v.*) of Dreux.

When the English barons revolted against John (1215), Louis of France was invited by them to take the English throne. He landed in England in 1216, but the enterprise was ultimately unsuccessful, and the barons gradually rallied round the infant Henry III after John's death (*see* Louis VIII).

The Matrimonial Conflict with the Papacy.—Several years before he tried to take advantage of the papacy's quarrel with John, Philip Augustus had himself been in dispute with Rome. After the death (1190) of Isabella of Hainaut, he had married Ingeborg, sister of the Danish king Canute VI, on Aug. 14, 1193; but next day, for some private reason, he had resolved to separate from her. Having procured the annulment of his marriage by an assembly of bishops in November 1193, he took a Tirolese lady, Agnes, daughter of Bertold IV of Meran, as his wife in June 1196. Denmark meanwhile had complained to Rome about the repudiation of Ingeborg, and Pope Celestine III had countermanded it in 1195; but Celestine died (1198) before he could resort to coercion against Philip. The next pope, Innocent III, was sterner: in January 1200 he imposed an interdict on France. Philip therefore in September 1200 had to submit, pretending to be reconciled with Ingeborg. In fact he refused to cohabit with her and kept her in semicaptivity till 1213, when he accepted her beside him—not as his wife but at least as his queen. Agnes had died in 1201, after bearing two children to Philip: namely Marie, countess of Namur (1211) and duchess of Brabant (1213) by successive marriages; and Philip, called Hurepel, count of Clermont (-en-Beauvaisis).

The Northeastern Frontier and Languedoc.—It was not only at the Plantagenets' expense that Philip enlarged the royal domain. His claim to Artois through his first marriage and his gains by the settlement of 1185–86 have been mentioned above, and he subsequently proceeded, step by step, to acquire the rest of Vermandois and Valois. His regular insistence on his suzerainty over vacant fiefs and on his tutelage over minors and heiresses was particularly effective with regard to Flanders, since not only Philip of Alsace (d. 1191) but also Baldwin IX, who disappeared as a prisoner of the Bulgars (1205), left no male issue.

Though he did not personally take part in the "Albigensian crusade" against the Cathari in Languedoc, Philip Augustus allowed his vassals and knights to carry it out. Simon de Montfort's capture of Béziers and Carcassonne (1209) and his victory at Muret over Raymond VI of Toulouse and Peter II of Aragon (1213) prepared the way for the eventual annexation of eastern Languedoc to the royal domain six years after Philip's death and checked Aragonese ambitions in southern France.

Internal Affairs.—Throughout his reign Philip Augustus kept a close watch over the French nobility, which he brought effectively to heel. He maintained excellent relations with the French clergy, leaving the canons of the cathedral chapters free to elect their bishops and favouring the monastic orders. He knew too how to win the support of the towns, granting privileges and liberties to merchants and upholding the communal movement, which weakened the seigniorial authority of the nobles (*see* Commune [Medieval]). In return, the communes helped him financially and militarily: for instance, the militias of his Picard communes were present at Bouvines. Most of all, Philip gave his attention to Paris (*q.v.*), not only fortifying it with a great rampart but also having its streets and thoroughfares put in order. For the countryside, he multiplied the number of *villes neuves* ("new towns"), or enfranchised communities, on the already established pattern of the one at Lorris-en-Gâtinais.

The Capetian monarchy's hold on the huge royal domain and on the kingdom as a whole was considerably strengthened by Philip's institution of a new class of administrative officers, the royal *baillis* and the seneschals for the provinces, who were appointed by the king to supervise the conduct of the local *prévôts* ("provosts"), to give justice in his name, to collect the revenues of the domain for him, to call up the armed forces, etc.

Conclusion.—Philip II Augustus died at Mantes on July 14, 1223. His political ability and the indefatigable energy with which

he had accomplished an immense work on all fronts had made him in fact supreme in his kingdom, where the Capetian dynasty's authority was henceforth more or less incontestable. Knowing his own strength, he was the first of the Capetians not to have his eldest son crowned and associated with him during his lifetime.

PHILIP III LE HARDI OR THE BOLD (1245–1285), king of France from 1270, was born on April 30, 1245, the second son of Louis IX of France and Margaret of Provence. Heir to the crown from the death of his brother Louis (1260), he was married in May 1262 to Isabella, daughter of James I of Aragon. Accompanying the crusade against Tunis, he was in Africa when Louis IX's death (Aug. 25, 1270) made him king. Having made a truce with the Muslims (Oct. 1270), he set off for France via Italy. On the journey Isabella of Aragon died at Cosenza, as the result of a miscarriage, in January 1271. Philip was anointed at Reims on Aug. 15, 1271.

Mathieu de Vendôme, abbot of Saint-Denis, whom Louis IX had left as regent in France, was maintained in control of the administration. The first important matter was the annexation to the French crown of the immense inheritance of Alphonse (*q.v.*) of Poitiers, and his wife, the heiress of Toulouse, who both died in Aug. 1271. This was accomplished, pending settlement of rival claims.

The king's personal entourage, meanwhile, was at first dominated by the chamberlain Pierre de La Broce, whose aggrandizement and accumulation of riches provoked envy. But in August 1274 Philip married his second wife, Mary, daughter of the duke of Brabant (Henry III); and she made herself the focus at court of a princely faction hostile to La Broce. When the prince Louis, Philip's eldest son by his first marriage, died suddenly in 1276, La Broce spread a report that he had been poisoned as a step toward clearing the way to the crown for Mary's children. For evidence, he concocted supernatural revelations allegedly made to some nuns in the Netherlands. The fraud was detected, and La Broce, whom Mary's friends also accused of treasonable relations with Castile, was arrested in January 1278, and hanged on June 30.

Revolts in Foix and Armagnac (1272) had been suppressed without much trouble; and Philip maintained correct relations with Edward I of England, notwithstanding crises that arose over their vassals in Limoges and in Béarn (1273–74) and Edward's claim to part of the Poitiers-Toulouse succession. More important were the affairs (1) of Champagne and Navarre and (2) of Castile.

Henry III, count of Champagne, who was also king of Navarre as Henry I, died in 1274, leaving his widow, Blanche of Artois, as regent for his infant daughter Joan. Though Joan had been promised first to an English prince, then to an Aragonese, Blanche in May 1275 concluded the Treaty of Orléans with Philip, betrothing Joan to one of Philip's sons and agreeing that Philip should govern Navarre till Joan's majority. In 1276 there was a serious revolt against the French regime in Navarre; but Joan's marriage (1284) to the future Philip IV of France led to the reunion of Champagne and the royal domain and to a personal union of the French and Navarrese crowns.

Blanche of France, Philip's sister, had two sons by her husband Ferdinand (Fernando de La Cerda), heir apparent to Alfonso X of Castile. (*See* ALFONSO.) When Alfonso, on Ferdinand's death (1275), overruled the rights of Blanche's sons and recognized their uncle Sancho as his heir instead, Philip went to war for his nephews. In the autumn of 1276 a great army was mustered round the king at Sauveterre, in Béarn; but it never crossed the Pyrenees, as diplomatic pressures and suggestions of treachery induced the king to abandon the project in December. Punctuated by truces, the state of war between France and Castile outlasted Philip's reign.

By the Treaty of Amiens (May 1279), Philip ceded Agenais to Edward I of England, undertook to investigate his rights to lands in Quercy and recognized his succession by right of his wife, Eleanor of Castile, to the countship of Ponthieu. This was a success for the queen mother, Margaret of Provence, who always supported a pro-English policy. Thereafter the party of Mary of Brabant steered French policy along a line favourable to Philip's uncle, Charles of Anjou, despite Margaret's persistent hostility toward him.

The War of the Sicilian Vespers (*q.v.*) broke out in 1282. Impelled by Mary's faction, Philip lent himself to the papacy's appeal for a crusade against Peter III of Aragon. Having accepted Pope Martin IV's offer of Aragon for his son Charles (*q.v.*) of Valois in Feb. 1284, Philip advanced with his army into Roussillon in May 1285 and crossed the Pyrenees into Catalonia in June. Harassed by guerrillas and exposed to malaria, the crusaders besieged Gerona, which held out till September. Then the destruction of their fleet off the coast by Ruggiero di Lauria made retreat inevitable. On Oct. 5, 1285, the king died of fever at Perpignan.

Philip III left two sons by Isabella of Aragon, namely Philip IV of France and Charles of Valois, and three children by Mary of Brabant, namely Louis, later count of Évreux (d. 1319), Margaret, married in 1299 to Edward I of England, and Blanche, married in 1300 to Rudolf III of Austria.

See C. V. Langlois, *Le Règne de Philippe III le Hardi* (1887).

PHILIP IV LE BEL OR THE FAIR (1268–1314), king of France from 1285, was born at Fontainebleau, the second son of King Philip III by Isabella of Aragon. The death of his elder brother Louis in 1276 made him heir apparent to the French crown; and on his marriage (Aug. 16, 1284) to Joan of Navarre and Champagne he immediately assumed the title of king of Navarre and count of Champagne. He became king of France on his father's death on Oct. 5, 1285.

Aragon, England, and Flanders.—Philip IV, who had disapproved of his father's disastrous "crusade" against Aragon (1284–85), set himself to make peace with the new Aragonese king, Alfonso III. But their quarrel was part of the wider discord unleashed in the War of the Sicilian Vespers (*q.v.*); and their treaty of Brignoles (February 1291) was repudiated by Alfonso's successor, James II. Peace, however, was finally concluded with the treaty of Anagni (June 1295).

PHILIP IV, ALSO CALLED "PHILIP THE FAIR." STATUE FROM HIS TOMB IN THE BASILICA OF SAINT-DENIS

Meanwhile, Philip's relations with Edward I of England had deteriorated. In 1293 there were skirmishes at sea between French and English or Gascon fleets, and Philip summoned Edward, his vassal for the duchy of Guienne, to answer at his court. On the excuse of Edward's nonappearance, Philip announced the confiscation of Guienne (May 1294) and sent an army to invade the duchy. By 1296 almost all Guienne was in French hands, and in 1297 Philip and Edward made a truce.

Philip was also attempting to increase his influence in Flanders, and to this end he supported the town oligarchies against the count of Flanders, Guy of Dampierre. In 1297 he demanded the cession of certain border towns. Guy's refusal and his alliance with Edward I led to a French invasion of Flanders, the royal army occupying the main cities. When Philip came to more definite terms with Edward and evacuated Guienne under the Treaty of Montreuil (1299), Guy was isolated; and in May 1300 he surrendered to Philip, who was thus left in virtual control of Flanders. The Flemish towns, however, resented the

French king's authority as much as the count's; and on May 18, 1302, the French in Bruges were massacred (the "Matins of Bruges"). An army sent to avenge them was defeated at Courtrai in July 1302, and Philip himself had to lead another army to Flanders. He defeated the Flemings at Mons-en-Pévèle (Aug. 18, 1304) and forced them to accept the oppressive Treaty of Athis-sur-Orge (June 23, 1305). Guy's son Robert of Béthune was recognized as count of Flanders, but his subjects were pledged to assist France—if need be, against him; some town walls were demolished, French troops occupied certain places, and heavy indemnities and services were exacted. Though Philip had won, Flemish opposition to Capetian rule remained strong.

The Eastern Frontier.—Philip IV also extended royal control elsewhere on his eastern frontier. Henry III of Bar, who had allied himself with Edward I and attacked Champagne (1296–97), was taken prisoner and released only in 1301 on his acknowledging Philip's suzerainty over certain lands west of the Meuse (*see* BAR, COUNTS AND DUKES OF). With regard to Lyons and the Lyonnais, Philip supported the townsmen against their archbishop from 1290, then accepted the archbishop as his vassal in 1307, and finally obtained complete sovereignty in 1312, notwithstanding the rights of the church or of the Holy Roman emperor's kingdom of Arles. In 1307 likewise, after long pressure, French control was recognized over the Vivarais, that is, the bishopric of Viviers and its dependencies along the right bank of the Rhône in northeastern Languedoc.

The Conflict with the Papacy.—Philip's most spectacular contest was with the Holy See. His relations with it had originally been cordial, but in 1296 a dispute broke out over the titles which Philip sought to levy from the clergy of France. The popes had hitherto allowed the clergy to contribute to the cost of crusades against Muslims, against heretics (such as the Cathari), or against the Aragonese in the matter of Sicily; and they could even be taxed "for the defense of the realm." Then the Cistercians, always heavily taxed, protested to Pope Boniface VIII. Boniface, a curt authoritarian who was convinced of the absolute sovereignty of the Holy See, thereupon issued the bull *Clericis laicos* (February 1296), forbidding clergy to pay subsidies to lay authorities without his express permission. Philip retaliated by prohibiting the export of gold or silver from the country, so that the papacy would not receive its customary dues. The pope's next bull, *Ineffabilis amor* (September 1296), was more conciliatory, and in 1297 he allowed the French clergy to contribute for the Flanders campaign.

In 1301 a more serious conflict began. Bernard Saisset, whose diocese of Pamiers had been carved from that of Toulouse by the pope's orders, was denounced to Philip by the bishop of Toulouse and was brought before the king's court at Senlis in October 1301. He admitted speaking against the king, and it is conceivable that he had, as was alleged, intrigued with the Aragonese; but further charges of heresy and simony seem to have been unwarranted. Boniface, to whom Philip sent a list of Saisset's alleged crimes, retorted in December with *Salvator mundi* and *Ausculta fili*, which withdrew all privileges from the king of France, and summoned French prelates to a council to be held at Rome in November 1302. Philip convened an assembly of barons, prelates, and town representatives in April 1302, at which it was decided to boycott Boniface's council; and a letter was sent to Boniface denouncing him as an intruder in the Holy See, as the former pope, Celestine V, who had abdicated, had died in confinement under Boniface. (*See* CELESTINE.) Boniface then issued the bull *Unam sanctam* (November 1302), defining his supreme authority, and prepared to excommunicate Philip. But, before the sentence was pronounced, Philip sent a small force to Italy, led by one of his counselors, Guillaume de Nogaret (*q.v.*). Nogaret's men and their accomplices surprised the pope at Anagni (Sept. 7, 1303), did him some violence, and held him prisoner till the local populace released him two days later.

Boniface died in Rome on Oct. 11, 1303. His successor, Benedict XI, reigned for less than a year; and Philip was able to enforce a conciliatory attitude on the next pope, Clement V, by the perpetual threat of pressing the question of Boniface's legitimacy of office. Clement annulled the bulls *Clericis laicos* and *Unam sanctam*, thus conceding outright victory to the secular power in its conflict with the church. Philip and his advisers had, indeed, no intention of allowing the church to meddle in secular affairs, though they of course recognized its jurisdiction in matters of conscience.

The Government of France.—Philip IV had collected around him a group of very able counselors, in particular the so-called "légistes," who were men trained in Roman law and therefore familiar with the idea of an all-powerful state. Servants of proved fidelity, they could also wield authority. Among them were Pierre Flote, keeper of the seals in the first part of the reign; Guillaume de Nogaret, keeper of the seals after 1307; the jurist Guillaume de Plaisians; and Enguerrand de Marigny, who administered the finances.

The national assemblies which Philip convened to strengthen his government were the forerunners of the French estates-general. After the assembly of 1302, called to range France with him against the pope, two more assemblies of nobles, prelates, and town representatives discussed ecclesiastical problems in 1304; and in 1308 the affair of the Templars was discussed at an assembly at Tours. The work of the *parlement* (*q.v.*) grew more specialized, and the chancellery became increasingly important as an office of government in Philip's reign. But Philip's influence was most clearly felt in the sphere of finance. He reformed the central fiscal administration and, in 1303, created the *chambre des comptes* (*camera compotorum:* chamber of accounts) as a sovereign court. Determined to increase his revenue, he enforced the regular collection of direct and indirect taxes, laying particular stress on the so-called *maltôte*, a tax begun by Louis IX by which the crown claimed one *denier* in the *livre* on every commercial transaction. He also revived the *fouage*, a land tax for war subsidies, not employed since Charlemagne's time. Philip's fiscal measures, however, provided insufficient revenue, and he resorted to debasement of the coinage. In 1295 and 1296 the quality of gold coins was debased and silver coins were reduced in size. A further debasement occurred in 1303, when the value of the royal *gros Parisis* fell by 50%; but this alarmed the merchants, and in 1306 a reverse policy of deflation was carried through. Then in 1311 the currency was again debased, before a better coinage was restored in 1313.

Philip exacted vast sums from Jews and Lombards. The Jews paid him 100,000 *livres* in 1292 and 215,000 *livres* in 1295, in 1299, in 1302, and in 1303; and in 1306 they were arrested and their assets appropriated. The Lombards were all imprisoned in 1291 and 1311, and were only released on the payment of heavy subsidies.

The Affair of the Templars.—His desperate need for money may have been the reason why, in October 1307, Philip arrested all the Templars (*q.v.*) in France; for they were immensely rich. An excuse lay ready to hand in the accusations of heresy and unnatural vice currently leveled against the Templars. Informed by Philip of the charges, Pope Clement V ordered an inquiry and decided that the Templars were to be interrogated by churchmen. Nevertheless, partly by threatening to revive the case against Boniface, Philip contrived to force the pope's hand; and some Templars, who had retracted their earlier confessions, were burned as relapsed heretics in May 1309. In April 1312 Clement suppressed the Order, and in May 1314 its leading dignitaries in France, including the grand master, Jacques de Molay, were burned by royal officials.

The King's Daughters-in-Law.—The end of Philip's reign saw one last sombre incident, a notorious scandal in the royal family. Philip's eldest son, the future Louis X of France, had been married to Margaret, daughter of Robert II, duke of Burgundy; and the younger sons, later Philip V and Charles IV, had been married respectively to Joan and to Blanche, daughters of Otto IV, count of Burgundy (Franche-Comté). Margaret, Joan, and Blanche were arrested on charges of adultery in May 1314, and Joan alone was acquitted by the *parlement*, the others being convicted and imprisoned.

Conclusion.—Philip died on Oct. 29, 1314, at Fontainebleau.

Few kings have been so variously judged. Some historians have treated him as insignificant, the pawn of his counselors and interested only in hunting. Recently, however, he has come to be regarded as a skilful statesman who forcefully continued the centralizing work of Philip II and Louis IX. Pragmatical, given to intrigue, taciturn and cynical, he yet showed more than conventional piety; his nickname "the Fair" is testimony of his outstanding good looks.

(M. PAC.)

PHILIP V LE LONG OR THE TALL (1293 or 1294–1322), king of France from 1316, was the second son of King Philip IV by Joan of Navarre and Champagne. He was married in January 1307 to Joan (d. 1330), elder daughter of Count Otto IV of Burgundy (Franche-Comté) by Mahaut of Artois. In December 1311 his father made him count of Poitiers. His wife was accused of adultery in 1314, but was acquitted, whereas his brothers' wives were found guilty.

While Philip was on a mission to the conclave at Lyons, his elder brother, King Louis X, died in the night of June 4–5, 1316, leaving (1) a four-year-old daughter, Joan (Jeanne), by his adulterous first wife and (2) a pregnant widow, Clémence of Hungary. In this unprecedented situation the regency of France was claimed by Charles of Valois, as the eldest male of the royal house, and by Eudes IV, duke of Burgundy, as the infant Joan's maternal uncle. Philip, however, reached Paris on July 12, won the support of the officers of the crown and of the bourgeois, and seized the royal palace. On July 16 an assembly of princes and magnates accepted him as regent till the majority of the unborn child: if that child should be a daughter, her claims, together with her half sister's and Philip's, were then to be adjusted. The Treaty of Vincennes (July 17) gave the custody of the infant Joan to Eudes, who in September was betrothed to Philip's eldest daughter, another Joan.

Clémence produced a son, John I (*q.v.*), but he died five days later (Nov. 19, 1316). Thereupon Philip declared himself king, regardless of his niece Joan's rights. The duke of Burgundy and Philip's own brother, the future Charles IV of France, refused to attend Philip's anointing at Reims (Jan. 9, 1317); but on Feb. 2 an assembly of barons, prelates, Parisian bourgeois, and doctors of the University of Paris recognized Philip as king. (*See* also SALIC LAW OF SUCCESSION.)

Philip and his brother Charles were reconciled when the death of Philip's only son (Feb. 18, 1317) made Charles the heir presumptive under the existing arrangement. The Burgundians and the infant Joan's partisans in Champagne, who had taken up arms, came to terms with Philip in March 1318. In Artois, where the rule of Mahaut was contested by her nephew Robert III, order was restored in July 1319. The count of Flanders, Robert of Béthune, to whom Philip in 1316 had offered to review the oppressive treaty of Athis-sur-Orge (1305), was on the brink of war from 1318, but did homage to Philip in April 1320. Edward II of England did a form of homage for his French fiefs at Amiens on June 20, 1320.

The assembly of February 1317 was hardly representative of the kingdom as a whole. Philip convened seven more assemblies, some regional, some more limited, but they assumed no political character and were mainly consulted on monetary questions or finance. The king tried to restore the royal power to what it had been before Louis X; he strengthened the local militias, under officers approved by the crown; and he was zealous for the redressing of grievances and for the efficient administration of justice. Yet he could do little against the Pastoureaux (*q.v.*) in 1320; and his ordinance of June 1321 against the lepers, who were alleged to be conspiring with the Moors for the ruin of Christendom, authorized an atrocious persecution.

Philip V died in the night of Jan. 2–3, 1322. Besides Joan (d. 1347), duchess of Burgundy by her marriage, he left two other daughters: Margaret (d. 1382), countess of Flanders by her marriage to Louis of Nevers; and Isabella (d. 1345), who was married to Guigues VIII, dauphin of Viennois.

See P. Lehugeur, *Histoire de Philippe le Long*, 2 vol. (1897–1931).

PHILIP VI (1293–1350), king of France from 1328, the first king of the Valois dynasty, was the elder son of Charles (*q.v.*) of Valois by Margaret of Naples-Sicily. Nephew of King Philip IV, he was first cousin to the brothers Louis X, Philip V, and Charles IV, the last Capetian kings of the direct line. Count of Le Mans (or of Maine) from 1315, he succeeded to the countships of Valois and of Anjou after his father's death, which took place in December 1325. He had been married in July 1313 to Joan, daughter of Duke Robert II of Burgundy.

Though Philip was Charles IV's closest kinsman by male descent, his right to the crown was contested by several claimants when Charles IV died (February 1328). In particular, there was support for Edward III of England, whose mother was the daughter of Philip IV. An assembly of magnates, however, not without bargaining, determined (1) that Philip should be regent till the end of the pregnancy of Charles IV's widow; and (2), as the widow produced a daughter on April 1, 1328, that Philip should be king. He was crowned at Reims on May 29, 1328. (*See* SALIC LAW OF SUCCESSION.)

On behalf of Louis of Nevers, count of Flanders, Philip led an army against the rebellious Flemings and defeated them in the Battle of Cassel (Aug. 23, 1328). Then a dispute arose in the king's immediate entourage. Robert of Artois, who had helped Philip to win the crown, claimed the countship of Artois against Joan of France (granddaughter of the countess Mahaut) and her husband Eudes IV, duke of Burgundy (Philip VI's brother-in-law). Philip had to institute judicial proceedings against Robert, who became his bitter enemy. Eventually Robert went to England (spring 1334) and began to incite Edward to claim the French crown.

Though Edward did homage to Philip for his French fiefs in 1329 and in 1331, Anglo-French relations deteriorated rapidly from 1334, partly because of Robert, partly because of the continuing French occupation of lands in Guienne, and partly because of France's support of the Scots. Philip in May 1337 declared Edward to have forfeited Guienne; and Edward in October 1337 assumed the title of king of France. Thus began the Hundred Years' War (*q.v.*).

Military operations were at first restricted; the English sacked or besieged towns in northern France; the French seized castles in Guienne. In 1340, however, France suffered a grave defeat in the naval battle of Sluys. In 1341 the war shifted to Brittany, where Charles of Blois, backed by Philip, and John of Montfort, backed by Edward, were contesting the ducal succession. Mediation by Pope Clement VI's envoys procured the Anglo-French truce of Malestroit (January 1343).

France's internal situation had worsened. Philip had been obliged, from 1335, to pack his council with nominees of the duke of Burgundy; and this Burgundian tutelage was almost insufferable to many of the king's subjects, especially in western France. A serious crisis resulted in 1343, and Philip had to act with severity against baronial revolts in Normandy and Brittany. The estates of the kingdom, summoned to Paris, took some measures to appease public opinion and to reduce the burden of administration. Men less subservient to Burgundy were taken into the council.

The truce of Malestroit, which had scarcely been observed in Brittany, lasted little more than two years. In summer 1345 the earl of Derby (Henry of Grosmont, soon to be duke of Lancaster) launched an offensive from Bordeaux and ravaged Périgord, Agenais, and Bazadais; and in 1346, while a French army in the south was trying in vain to take the little fortress of Aiguillon (northwest of Agen), Edward III landed in Normandy. After

threatening Paris, Edward turned northeastward into Ponthieu, where Philip, in pursuit of him, was heavily defeated in the Battle of Crécy.

This defeat, in which numbers of the French nobility perished, gave rise to another political crisis. To conciliate its opponents, the government undertook to reorganize the *chambre des comptes;* and control of the finances was entrusted to three abbots—those of Saint-Denis (Gille Rigaud), of Marmoutier (Simon Le Maire), and of Corbie (Hugues de Ver). Moreover, John, duke of Normandy, Philip's son and heir apparent, was excluded from public affairs, and a dynastic arrangement with Edward, to John's disadvantage, was contemplated. By May 1347, however, John had recovered his position, which thenceforward grew steadily stronger.

Meetings of estates had taken place in Paris (February 1346) and in Toulouse (February and May). After the fall of Calais to the English (August 1347), a new meeting was summoned to Paris for Nov. 30, 1347. This assembly, which seems to have been extremely hostile to the king's counselors, forced the king to promise the reestablishment of a sound currency and to accept the resignation (January 1348) of his chancellor, Guillaume Flote, who had been ten years in office. The council was again recast, with the admission of men who would promote the necessary reforms. Then the spread of the Black Death in 1348 and 1349 distracted men's minds from political questions.

Philip VI died on Aug. 22, 1350. His first wife, Joan of Burgundy, had died in December 1349, leaving two sons, the future John II (*q.v.*) and Philippe (1336–75; *see* Orléans, Ducs d'); other children had predeceased her. By a subsequent marriage to Blanche of Navarre (d. 1398), Philip had a posthumous daughter, Blanche.

Philip VI was a man of positive and methodical character who preferred the ways of diplomacy to war. Reigning at a difficult time, he had to bow before events stronger than his will and to witness an important development of the political power of the estates. Though he left a kingdom divided and weakened by war and plague, he yet had expanded its territory: he purchased Montpellier from James III of Majorca in 1349; and transactions with Humbert II of Viennois culminated in the sale of Dauphiné to Philip's grandson, the future Charles V, in 1349 likewise. Philip also continued the efforts of the 13th-century Capetians toward the progressive centralization of the administration in Paris. But Philip had no means of imposing on his kingdom the measures necessary for the maintenance of his monarchical power. To raise taxes for war he was obliged to make concessions to nobility, clergy, and bourgeoisie. The bourgeoisie, profiting from the king's power, proved grateful and loyal enough; it was chiefly among the clergy and nobility that the movement for reform took root.

See R. Cazelles, *La Société politique et la crise de la royauté sous Philippe de Valois* (1958). (R. Cs.)

PHILIP (*c.* 1177–1208), German king from 1198, also duke of Swabia from 1196, was the youngest son of the Holy Roman emperor Frederick I Barbarossa, of the Hohenstaufen dynasty, and Beatrix of Upper Burgundy (Franche-Comté). Destined for the church, he was appointed provost of the cathedral at Aachen and, in 1190 or 1191, elected bishop of Würzburg; but he soon renounced his ecclesiastical career. His brother, the emperor Henry VI, made him duke of Tuscany in 1195 and duke of Swabia in 1196; and in May 1197 he was married to Irene, daughter of the Byzantine emperor Isaac II Angelus and widow of Roger II of Sicily.

When Henry VI died in September 1197, his son, the future emperor Frederick II, was not yet three years old, and the German princes were unwilling to accept a child as king. So, while the Hohenstaufens' Welf rivals, namely the brothers Henry and Otto of Brunswick, were absent from Germany, Philip rather than Frederick was elected German king at Mühlhausen on March 8, 1198. Since the archbishop of Mainz was absent, however, the right of crowning the king belonged to Archbishop Adolf of Cologne; and he was leader of the anti-Hohenstaufen party, which in June proceeded to elect one of the Welf brothers as king. The Welf was crowned as Otto IV (*q.v.*) at Aachen, the proper place for the ceremony, by Adolf in July. Philip's coronation, by another prelate, did not take place till Sept. 8, 1198, at Mainz.

In the consequent warfare the Hohenstaufen cause at first prospered. However, Pope Innocent III, who claimed to be the arbiter of the conflict, in 1201 recognized Otto as king and excommunicated Philip. Then Otakar I of Bohemia deserted Philip's side, as Hermann of Thuringia had already done. Philip's fortunes thus waned till 1204, when they were restored by a series of defections from Otto's side, culminating in that of Adolf of Cologne himself. On Jan. 6, 1205, Adolf crowned Philip at Aachen.

The town of Cologne, which had stood for Otto despite its archbishop, submitted to Philip in January 1207, and Otto's cause seemed lost. Innocent, to whom Philip had long been making overtures, acknowledged him as king early in 1208. Philip was preparing a decisive stroke against Otto in Brunswick when he was murdered in Bamberg, on June 21, 1208, by Otto of Wittelsbach, count palatine for Bavaria, to whom he had refused to give one of his daughters in marriage. His eldest daughter, Beatrix (d. 1212), was betrothed to the Welf Otto in 1209 as a step toward reconciling the factions; the second, Kunegunda (d. 1248), married the Premyslid Vaclav I, king of Bohemia; the third, Maria (d. 1235), married Henry II of Brabant; and the fourth, Elizabeth, later known also as Beatrice (d. 1235), married Ferdinand III of Castile. A brave man, Philip was praised by contemporaries for his mildness and generosity. The diversion of the Fourth Crusade to Constantinople is sometimes thought to have been prompted by him in the interests of his brother-in-law, the Byzantine emperor Alexius IV.

As well as works cited under Otto IV, *see* O. Abel, *König Philipp der Hohenstaufe* (1852); A. Luchaire, *Innocent III,* vol. iii (1906).

PHILIP II (382–336 B.C.), son of Amyntas III, king of Macedonia, made his country predominant in Greece and laid the foundations for its expansion under his son Alexander III (*q.v.*) the Great. As regent to his nephew Amyntas on the death of his brother Perdiccas III in 359 (for the dynastic history, *see* Macedonia, Kingdom of: *The Argeads to 336 B.C.*), he suppressed various rivals by generalship and cunning diplomacy and defeated first the Paeonians, then the Illyrians who had overrun Lyncestis (around modern Bitola, Yugos.). Probably in 356 by popular consent he was hailed king in his own right. As a youth Philip had passed three years (367–365) as a hostage in Thebes; his admiring acquaintance with Epaminondas there may have inspired the reforms which now transformed the Macedonian army into a formidable weapon of expansion. Philip's first moves led him eastward into an area where Athens was deeply committed. In 357 he took Amphipolis, and from 356 onward the possession of Crenides (which he renamed Philippi) gave him control over the gold and silver deposits of Mt. Pangaeus, which were to produce 1,000 talents a year, thus furnishing the mainstay of his military budget and of a diplomacy in which bribery and corruption were to loom large. Meanwhile Philip's seizure of Potidaea in Chalcidice (356) and of Pydna (356) and Methone (354) on the Thermaic Gulf rounded off Macedonian power along the coast to the further detriment of Athens. But the Athenians, divided internally by rival policies, preoccupied with revolts of their allies, and outmaneuvered by Philip's unscrupulous diplomacy, took no effective action.

During the next nine years (354–346) Philip gained a firm foothold in central Greece, where the still dominant Thebans shortsightedly welcomed intervention against their enemies in the neighbouring state of Phocis. The seizure of Delphi and its temple treasures by the Phocians, who used them to hire a large mercenary army, led the Aleuadae of Larissa in Thessaly to appeal to Philip. After one setback in 353 he defeated the Phocian general Onomarchus at the Battle of the Crocus Field (*see* Greece: *History: Macedonian Period*), thus becoming virtually master of Thessaly; but a joint Greek army, containing contingents from Athens and Sparta, denied him access to Thermopylae. Philip countered with a new advance in the northeast, where he soon defeated Athens' Thracian allies and extended Macedonian influence to the

whole of Thrace between the Nestos River and the Black Sea. Next, between 351 and 348, he turned on the Chalcidian League, which had earlier connived at his seizure of Potidaea. Its chief city, Olynthus, now appealed for help to Athens, but despite Demosthenes' vigorous oratory the help sent was too little and came too late, and in 348 Olynthus fell. Philip meanwhile hamstrung Athenian resistance by stimulating a revolt against Athens in Euboea. Eventually in 346 the Athenians sent envoys to Pella and the so-called Peace of Philocrates was sworn. This left Philip free to complete the defeat of Phocis, and he emerged as the dominant figure in central Greece, with a seat on the amphictyonic council controlling Delphi (*see* AMPHICTYONY).

Between 345 and 340 Philip carried out a determined campaign to consolidate and extend his position in Greece. His education had been Greek and as an Argead he claimed descent from Heracles. The recognition implicit in his presidency of the Pythian Games (346) thus brought him great satisfaction. Hence he appears to have shrunk from a purely military solution of his problems, which could have been maintained only by garrisons and suppression, and to have preferred a subtle policy of diplomatic insinuation and the exploitation of internal differences among the parties in the Greek cities. At Athens the publicist Isocrates turned to him as the potential leader of a crusade against Persia, which would open up Asia Minor for Greek colonization; and such plans may already have been in Philip's mind, though hardly in the form in which Isocrates, concerned only for the Greeks, conceived them. Meanwhile Demosthenes devoted himself to whipping up an anti-Macedonian coalition, in which he saw the only hope of a secure, independent Athens.

Philip used the lull to extend his power to the west and to the south. In Epirus, to which he was already linked by his marriage in 357 to Olympias, a princess of the royal house, he now won full control by expelling the ruling king, Arybbas, and putting Olympias' younger brother Alexander on the throne (342). In 344/343 he became archon of Thessaly for life, and reorganized the whole state under his personal domination; Thessaly was to remain an appendage of the Macedonian monarchy until 197 B.C. Demosthenes' campaign now received a fillip from the king's advance eastward toward the Bosporus, through which Athens' vital grain trade passed. From 341 onward Demosthenes succeeded in organizing a coalition including Chalcis, Corinth, Megara, Achaea, some northwestern Greek states, and in the northeast Abydos, Perinthus, and Byzantium. But most of the Peloponnesian states held aloof, and the Thebans, grateful for help against Phocis, remained Philip's hesitant ally. Philip's attack on Byzantium in 340 was followed by an Athenian declaration of war; and a confused conflict with Amphissa within the amphictyony afforded a pretext to bring Philip south to take the command in a new Sacred War. Now at last Demosthenes succeeded in winning over the Thebans, alarmed too late at Philip's proximity; but in August 338 Philip won a decisive victory at Chaeronea (*q.v.*) in Boeotia, where his well-timed use of cavalry and infantry routed the uncoordinated forces of Thebes and Athens.

As master of Greece Philip had to settle Greek affairs. Thebes was harshly treated and a Macedonian garrison installed; but toward Athens Philip was lenient, for he retained a genuine respect for the Athenian cultural tradition and, perhaps more important, the Athenians' fleet still made them a formidable enemy. His motives at this point were almost certainly mixed and even contemporaries discussed them without reaching unanimity. But at least it appears that he had now decided to attack Persia, having already broken off relations in 341 after the arrest and execution of his friend and ally, Hermeias of Atarneus. An anti-Persian crusade would require a consolidated and collaborative Greece, and to this end Philip now applied himself in a statesmanlike fashion. All the cities except Sparta quickly submitted; and in 338/337 a panhellenic congress was called to Corinth, where a common peace was established and a confederacy of Greeks set up, with a representative council (*synedrion*) and Philip as "leader" (*hegemon*). This confederacy was allied to Macedonia and served as an instrument of Macedonian domination in Greece. It brought Greece a stability it had failed to find while independent; but this did not last long, for the majority of the Greeks rejected a unity imposed by force from without. At a second meeting of the confederacy in 337 Philip announced the war against Persia, and in spring 336 an advance force of 10,000 crossed over into the Troad. But the same summer, at a feast held at Aegae to celebrate the wedding of his daughter Cleopatra with Alexander of Epirus, Philip fell murdered by one of his courtiers, Pausanias; this man may have been suborned by Olympias, whom Philip had recently repudiated (he had married a Macedonian, Cleopatra, in 337), but proof is lacking.

The historian Theopompus said with some justice that Philip was the greatest man Europe had yet produced. He had built up Macedonia by centralizing power in the monarchy, by reducing the authority of the principalities in the fringe areas, and by introducing territorial divisions into the national army organization; he had also secured it a seaboard by annexing Chalcidice and the Thermaic towns and had given it vast economic resources by his acquisition of the mines of Pangaeus in Thrace. Philip shared with his son Alexander the quality of high personal courage, and on various occasions he sustained serious wounds, including the loss of an eye at Methone. He was wholly tireless and campaigned readily at all seasons of the year. As a general he lacked Alexander's adaptability and sheer genius, and he probably owed much to reliable subordinates like Parmenio. But he developed siegecraft significantly and trained the army with which Alexander was subsequently to conquer much of Asia. Following the traditions of his country, he was a man of considerable sensuality and a heavy drinker; but his interests ranged beyond these pleasures. He assembled a mixed body of Greek and Macedonian "companions" (*hetairoi*) around him; he had a real love of Hellenic culture, and to educate his son Alexander he brought the philosopher Aristotle to Pella. In diplomacy he outstripped most of his contemporaries and was quite unscrupulous in his methods; he used marriage alliances as an instrument of policy, and his widespread distribution of money acquired for him supporters in every city. Ultimately he may well have intended to reduce both Macedonia and Greece to elements in a personal autocracy; but his reign introduced an age of Macedonian preeminence which was to end only in 197 when the phalanx was broken by the Roman legions at Cynoscephalae.

PHILIP V (238–179 B.C.), king of Macedonia, son of Demetrius II and his wife Phthia (Chryseis). On his father's death (229) Philip's half cousin Antigonus Doson adopted him, and when Antigonus died (summer, 221) Philip succeeded. He soon won renown in the war of the Greek alliance against Aetolia, Sparta, and Elis (220–217), and he asserted his personal control by executing several ministers for conspiracy in 218. After the Peace of Naupactus (217), incited by Demetrius of Pharos, he attacked the Roman client states in Illyria by sea and, after losing his fleet (214), by land. In 215 he made a treaty with Hannibal. The Romans countered this by an Aetolian alliance (211), and with the collaboration of Attalus of Pergamum soon gained an advantage in Greece; but Philip effectively aided his allies, and when the Romans withdrew in 207 he sacked Thermum and forced peace upon Aetolia (206). The Peace of Phoenice (205) ended the war in Philip's favour. He then turned to the east. He used a pirate, Dicaearchus, to obtain resources, plotted against Rhodes, and in 203/202 conspired with Antiochus III to plunder Ptolemy V's possessions. But the people of Rhodes and Pergamum defeated him by sea off Chios (201) and their exaggerated reports contributed to a Roman decision to make war. Philip meanwhile was attacking Athens and the Thracian Chersonese; but by September 200 a Roman army was in Illyria. Two campaigns in Macedonia (199) and Thessaly (198) shook Philip's position and detached his Achaean allies. In 197 at Cynoscephalae in Thessaly the Romans under T. Quinctius Flamininus defeated him, and by

the peace terms he was confined to Macedonia and had to surrender 1,000 talents indemnity and most of his fleet and deposit hostages, including his younger son Demetrius, at Rome.

From then until 189 Philip collaborated with Rome, sending aid against Nabis (195) and Antiochus and Aetolia (192–189), and winning back some places in Thessaly. He afforded the Scipios invaluable help in Macedonia and Thrace; consequently his outstanding tribute was remitted and his son restored (190). His last decade was devoted to consolidating his kingdom. He reorganized finance, transplanted populations, reopened mines, and issued central and local currencies. But his neighbours constantly accused him at Rome, and with success. Adverse decisions (185) seemed to foreshadow his destruction and accordingly he turned his attention to the Balkans, where he carried out three campaigns (184, 183, 181). Meanwhile Demetrius' pro-Roman policy precipitated a quarrel with the crown prince Perseus and Demetrius' execution as a traitor (180). In 179, while pursuing a scheme for directing the Bastarnae against the Dardanians, Philip died at Amphipolis.

Philip was a fine soldier and a popular king, at his best in adversity; but a lack of balance often led to political errors. He never neglected his northern frontiers, but his plans for expansion elsewhere, pursued without scruple, lacked consistent aim and encountered limited success. Hence his historical significance lies mainly as an episode in the expansion of Rome. *See* also MACEDONIA, KINGDOM OF: *The Antigonids, 277–168 B.C.*

PHILIP I THE HANDSOME (1478–1506), the first Habsburg king of Castile, was born at Bruges, in Flanders, on July 22, 1478, the son of the future Holy Roman emperor Maximilian I and Mary of Burgundy. At his mother's death, in 1482, he succeeded to her Burgundian (Netherlands) dominions, with Maximilian acting as regent for him during his minority. In 1496, at Lille, he was married to Joan (the Mad), daughter of Ferdinand V of Aragon and Isabella I of Castile. Recognized as prospective heir to the Spanish kingdoms in 1502, Philip was soon at variance with his father-in-law, who was unwilling to give up his own claims to the government of Castile. On Isabella's death (1504), Joan succeeded to the crown of Castile; and early in 1506 Philip sailed for Spain, to claim his wife's inheritance. His ships, however, had to take temporary shelter in Weymouth, and Henry VII of England forced him to sign the so-called *Intercursus Malus*, a trade agreement disadvantageous to the Netherlands. In Castile, Philip was supported by the majority of the nobles against Ferdinand, but he died suddenly at Burgos, on Sept. 25, 1506. His son, the future emperor Charles V, succeeded him in the Netherlands and, after Ferdinand's death in 1516, also in Spain.

PHILIP II (1527–1598), king of Spain from 1556, in whose reign Spain and the Spanish Empire attained their greatest power and widest geographical extent, was born at Valladolid on May 21, 1527, the son of the emperor Charles V and Isabella of Portugal. From time to time, the emperor wrote Philip secret memoranda, impressing on him the high duties to which God had called him and warning him against trusting any of his advisers too much. Philip, a very dutiful son, took this advice to heart. From 1543 Charles conferred on his son the regency of Spain whenever he himself was abroad. From 1548 until 1551, Philip traveled in Italy, Germany, and the Netherlands; but his great reserve and his inability to speak fluently any language except Castilian made him unpopular with the German and Flemish nobility.

Philip contracted four marriages. The first was with his cousin, María of Portugal, in 1543. She died in 1545 giving birth to the ill-fated Don Carlos (*q.v.*). In 1554, Philip married Mary I of England and became joint sovereign of England, until Mary's death, without issue, in 1558. Philip's third marriage, with Elizabeth of Valois, daughter of Henry II of France, in 1559, was the result of the Peace of Câteau-Cambrésis (1559), which for a generation ended the open wars between Spain and France. Elizabeth bore Philip two daughters, Isabella Clara Eugenia (1566–1633) and Catherine Micaela (1567–97). Elizabeth died in 1568 and, in 1570, Philip married another cousin, Anna of Austria, daughter of the emperor Maximilian II. She died in 1580, her only surviving son being the later Philip III.

King of Spain.—Philip had received the duchy of Milan from Charles V in 1540 and the Kingdoms of Naples and Sicily in 1554 on the occasion of his marriage to Mary of England. On Oct. 25, 1555, Charles resigned the Netherlands in Philip's favour, and on Jan. 16, 1556, the kingdoms of Spain and the Spanish overseas empire. Shortly afterward Philip also received the Franche-Comté. The Habsburg dominions in Germany and the Imperial title went to his uncle Ferdinand I. At this time Philip was in the Netherlands. After his army's victory over the French at St. Quentin (1557), at the sight of the battlefield he exclaimed, "How could my father like this?" From then onward he always preferred to achieve his aims by peaceful methods rather than by war, although he did not shrink from it when he judged it necessary.

After his return to Spain from the Netherlands in 1559 Philip never again left the Iberian Peninsula. From Madrid he ruled his empire through his personal control of official appointments and all forms of patronage. Philip's subjects outside Castile, thus, never saw him and they gradually turned not only against his ministers but against himself. This happened particularly in the Netherlands, in Granada, and in Aragon.

MANSELL—ALINARI

PHILIP II, KING OF SPAIN. DETAIL FROM A PORTRAIT BY TITIAN IN THE CORSINI GALLERY, ROME

System of Government.—By sheer hard work Philip tried to overcome the defects of this system. His methods have become famous. All work was done on paper, on the basis of *consultas*, that is, memoranda, reports, and advice presented him by his ministers. In Madrid, or in the gloomy magnificence of his monastic palace of El Escorial which he built (1563–84) on the slopes of the Sierra de Guadarrama, the king worked alone in his small office, giving his decisions or, as often, deferring them. Nothing is known of his order of work, but all his contemporaries agreed that his methods dangerously, and sometimes fatally, slowed down a system of government already notorious for its dilatoriness. Painstaking and conscientious, Philip's craving for ever more information hid an inability to distinguish between the important and the trivial and a temperamental unwillingness to make decisions.

This was coupled with an almost pathological suspicion of his most able and faithful servants. Margaret of Austria, duchess of Parma, the duke of Alba, Don John of Austria, Antonio Pérez, and finally Alessandro Farnese (*qq.v.*), to name only the most distinguished, suffered disgrace. "His smile and his dagger were very close," wrote his official court historian, Cabrera de Córdoba. It was no exaggeration; for, in the case of Juan de Escovedo, the secretary of Don John of Austria, Philip even consented to murder (*see* PÉREZ, ANTONIO). As a result, Philip's court became notorious for the bitterness of its faction fights. The atmosphere of the Spanish court did much to poison the whole Spanish system of government and this played no small part in causing the rebellions of the Netherlanders (1568–1609; *see* NETHERLANDS, THE: *History*), of the Moriscos of Granada (1568–70), and of the Aragonese (1591–92; *see* SPAIN: *History: The House of Austria.*)

Yet the "black legend" which, in Protestant countries, represented Philip II as a monster of bigotry, ambition, lust, and cruelty is certainly false. Philip's spare and elegant appearance is known

from the famous portraits by Titian and by Anthonis Mor (Sir Anthony More). A lover of books and pictures, an affectionate father to his daughters, he lived an austere and dedicated life. "You may assure His Holiness," Philip wrote to his ambassador in Rome, in 1566, "that rather than suffer the least damage to religion and the service of God, I would lose all my states and an hundred lives, if I had them; for I do not propose nor desire to be the ruler of heretics." This remark may be regarded as the motto of his reign. To accomplish the task set him by God of preserving his subjects in the true Catholic religion, Philip felt in duty bound to use his royal powers, if need be, to the point of the most ruthless political tyranny, as he did in the Netherlands. Even the popes found it sometimes difficult to distinguish between Philip's views as to what was the service of God and what the service of the Spanish monarchy.

Foreign Policy.—For the first 20 years of his reign, Philip sought to preserve peace with his neighbours in western Europe. He was fighting a major naval war with the Ottoman Empire in the Mediterranean and, from 1568, he was faced with rebellion and war in the Netherlands. From the late 1570s, his policy gradually changed. The death (August 1578) without heirs of his nephew, King Sebastian of Portugal, opened up the prospect of Philip's succession to Portugal. He had to conquer (1580) by force what he regarded as his just, hereditary rights, but the rest of Europe was alarmed at this growth in Spanish power. Both England and France gave increasing support to the rebellious provinces of the Netherlands. Gradually, in the 1580s, Philip became convinced that the Catholic religion in western Europe, and his own authority in the Netherlands, could be saved only by open intervention against England and France. To this end he fitted out the Armada (*q.v.*) which, with the help of the Spanish army in the Netherlands, was intended to conquer England (1588). He sent money and troops to support the League, the ultra-Catholic party in France, against Henry of Navarre and the Huguenots. He even claimed the throne of France for his daughter, Isabella Clara Eugenia, after the murder of Henry III in 1589. Again, even his Catholic allies found it difficult to distinguish between Philip's championship of the Catholic Church and of the interests of the Spanish monarchy.

All these plans failed. Henry of Navarre became a Catholic (1593) and Philip had to accept (Peace of Vervins, 1598) his succession as Henry IV of France. England and the northern Netherlands remained Protestant and unconquered. Yet Philip's reign as a whole was not a failure. He had defeated the great Ottoman offensive in the Mediterranean at the Battle of Lepanto (1571). In the Iberian Peninsula he had completed the work of unification begun by the "Catholic Kings," Ferdinand and Isabella. Most important of all, in his own eyes, he had won great victories for the Catholic Church. If England, Scotland, and the northern Netherlands were lost, the southern Netherlands (the modern Belgium) had been preserved. In Spain and Italy he had prevented the spread of heresy and his intervention in France was one of the factors which forced Henry IV to become a Catholic. When Philip II died at El Escorial on Sept. 13, 1598, Spain was still at the height of her power and it took almost another half century before it became finally clear that the Counter-Reformation would make no further major conquests.

PHILIP III (1578–1621), king of Spain from 1598, was born in Madrid on April 14, 1578, the son of Philip II by his fourth consort, Anna of Austria. Succeeding his father on Sept. 13, 1598, he married the Austrian archduchess Margaret at Valencia in April 1599. A representative of the so-called "Baroque pacifist generation," he sought peace in western Europe: as his father had finally made the Peace of Vervins with France, Philip III concluded the Treaty of London with England (1604) and the Twelve Years' truce with the United Provinces of the Netherlands (1609). In this policy he had the ready collaboration of his chief minister, the duque de Lerma (*q.v.*), till 1618, when Lerma was supplanted by his son Cristóbal, duque de Uceda. Peace in the west enabled the government to deal with the internal problem of the Moriscos (*q.v.*); but the expulsion of the Moriscos had a serious effect on the country's economy.

In Italy affairs were complicated (1) by the activities of the duke of Savoy, Charles Emmanuel I, which led to war over Montferrat (*q.v.*); and (2) by the attempts of Venice to undermine the Spanish position in the peninsula. The so-called "conspiracy of Venice" (1618) is a matter of controversy among historians: some see it as a real effort by Philip's viceroy of Naples, Pedro Téllez Girón, duque de Osuna, and his agents to subvert the Venetian republic; others see it as an invention of the Venetians to discredit Spain. The policy of peace for western Europe was in any case brought to an end by the outbreak of the Thirty Years' War in 1618, whereupon Philip gave his unconditional support to the Holy Roman emperor Ferdinand II and the Catholic German princes. The occupation of the Valtellina (1620), carried out on Philip's orders by his governor of Milan, the duque de Feria (Gómez Suárez de Figueroa), was intended to ensure communications between Italy and the Habsburg territories north of the Alps.

Philip signed a treaty with the shah of Persia, Abbas I, against the Turks (1602) and gave some encouragement to anti-Turkish movements in the Balkans. Against Morocco he made contact with the kings of Cuco, in the Atlas Mountains.

Having resided at Valladolid for the first years of his reign, Philip eventually fixed his court at Madrid. After a visit to Portugal (1619), he fell ill. He died at Madrid on March 31, 1621. For his children who survived infancy *see* HABSBURG: *Table III.*

See Matías de Novoa, *Historia de Felipe III*, in the *Colección de documentos inéditos . . .*, vol. 60 (1875); C. Pérez Bustamante, *Semblanza de un monarca y perfiles de una privanza* (1948); Ubieto-Reglà-Jouer, *Introducción a la historia de España* (1963). (J. Re.)

PHILIP IV (1605–1665), king of Spain from 1621, was born at Valladolid on April 8, 1605, the eldest son of Philip III of Spain and Margaret of Austria. He succeeded his father on March 31, 1621.

For the first 22 years of his reign, Philip's *valido* or chief minister was the conde-duque de Olivares (*q.v.*), who took the spread of the Thirty Years' War (*q.v.*) as an opportunity, not only for resuming hostilities against the Dutch at the end of the Twelve Years' truce of 1609 (1621), but also for an ambitious attempt to restore Spanish hegemony in Europe, in close alliance with the imperial branch of the Habsburg dynasty. The Spanish armies won some conspicuous victories, for instance the capture of Breda from the Dutch (1626) and the defeat of the Swedes and Weimarians at Nördlingen (1634); but France declared open war in 1635, and Spain's early successes were offset, from 1640, by the separatist rebellions of Catalonia and of Portugal, which provided the French with footholds in the Iberian Peninsula itself. There was also an abortive conspiracy by the Andalusian nobility in 1641.

Olivares was dismissed in 1643 and his place was then taken by Don Luis de Haro, who remained in power till his death. The course of events went worse for Spain, however: the French won great victories at Rocroi (1643) and at Lens (1648); there were insurrections in Palermo and in Naples (1647–48); a treasonable plot to detach Aragon from Philip's dominions came to light; and finally the Treaty of Münster (January 1648), whereby Spain recognized the independence of the United Provinces of the Netherlands, was followed by the Peace of Westphalia (October), whereby the imperial Habsburgs and their German allies came to terms with France, leaving Spain to fight on alone. The scheme of Olivares for a revival of Charles V's empire was brought to nothing. After 11 more years of war Spain had to accept the Treaty of the Pyrenees (1659), ceding to France several places in the southern Netherlands and on the Pyrenean frontier, Roussillon and part of Cerdagne in return for France's renunciation of Catalonia, which in any case had been almost entirely recovered by Philip's forces since Don John of Austria's entry into Barcelona in 1652. Con-

tinued attempts to reconquer Portugal were unsuccessful.

Soured by defeat, Spain sank into pessimism, isolationism, and retrospection. The so-called "problem of Spain" became the subject of argument between those who remained faithful to the Habsburg tradition and those who demanded a complete change of policy.

From the death of Don Luis de Haro (1661) to the close of the reign Philip had no *valido,* though he still received the advice of the nun, María de Ágreda (*q.v.*), whose long correspondence with him dealt both with spiritual matters and with affairs of state. He was twice married: first, in 1615, to the Bourbon princess Elizabeth (Sp. Isabel; d. 1644), daughter of Henry IV of France; secondly, in 1649, to the Austrian archduchess Maria Anna (Mariana; d. 1696), daughter of the Holy Roman emperor Ferdinand III. For the children of these marriages *see* HABSBURG: *Table III.* Philip also had numerous mistresses and several illegitimate children, the most famous of the latter being the second Don John (*q.v.*) of Austria, son of the actress Maria Calderón. A poet and a lover of the arts, Philip was the friend and patron of the painter Velázquez, whose works are the most glorious monument of the reign. Philip IV died in Madrid on Sept. 17, 1665.

PHILIP V (1683–1746), king of Spain from 1700 except for a brief period from January to August 1724, was the founder of the Bourbon dynasty in Spain. During his reign Spain regained much of its former influence in international affairs. He was born at Versailles on Dec. 19, 1683, the second son of the dauphin Louis (son of Louis XIV) and of Marie Anne, daughter of Ferdinand, elector of Bavaria. Philip's whole career was coloured by the fact that he was a grandson of Louis XIV and a great grandson of Philip IV, king of Spain. With his elder brother Louis, duc de Bourgogne, he was educated in France by François Fénelon, as a result of whose influence Philip always remained strongly averse to the immorality which had been prominent at the court of France in the youth of Louis XIV. He was also at all times scrupulously religious and had an abnormally tender conscience. The people who had the most influence on him were his two wives and his confessors.

Philip held the title of duc d'Anjou until 1700. In that year he emerged as a person of political importance when Charles II, the last Habsburg king of Spain, died without issue and in his will left Philip all his possessions: Spain, Spanish America, the Spanish Netherlands, and certain parts of Italy. Louis XIV's acceptance of this will, together with his refusal to exclude Philip from the line of succession to the French throne, provoked the War of the Spanish Succession (*q.v.*). Philip proceeded to Spain in 1701 as Philip V and aided by his heroic and very young wife María Luisa of Savoy, who bore him four sons, he earned a good military reputation and won the loyalty of the majority of the Spanish people. The Treaty of Utrecht (1713) deprived Philip of the Spanish Netherlands and of the Italian possessions of the Spanish Habsburgs, but left him the throne of Spain and Spanish America.

The death of María Luisa on Feb. 14, 1714, created a delicate problem. It was clear that whoever married the king would exercise very considerable influence on the policies of Spain. During the first 13 years of his reign France had a dominant influence on the Spanish court. The French ambassador had a place on the inmost council of state and the queen had been largely influenced by her chief lady of the bedchamber, the French princesse des Ursins. Though she was 72 years of age at the time of the death of María Luisa, her influence over Philip was so great that there were rumours that he would marry her. In fact Philip chose the young Princess Isabella (*q.v.*) Farnese, the niece and stepdaughter of the duke of Parma. Under the tuition of Giulio Alberoni (*q.v.*), the Parmesan envoy at Madrid, this inexperienced princess banished the princesse des Ursins at their first meeting (Dec. 23, 1714), before Isabella had even met her husband.

It was characteristic of Philip V that he did nothing to restore the fallen favourite. He was peculiarly cold blooded in his personal relationships. He showed no enduring friendship for the Spanish nobles who had supported his cause in the last years of Charles II, and he had no real friendship for his ministers. His only really intimate friend was his master of horse, the duque del Arco, who had saved his life while hunting. For a time the new queen shared her influence over the king with his confessor but, though Philip remained all his life extremely religious, the queen gradually came to exercise the greater influence over him. Isabella bore Philip four sons and three daughters, but since in 1714 Philip had three sons surviving from his first marriage there was little chance that Isabella's children would inherit the Spanish throne. For the rest of the reign, therefore, Spanish policy was directed partly by the dynastic ambitions of Isabella to obtain territories in Italy for her sons (*see* SPAIN: *History*). Isabella's eldest son, Charles (afterward Charles III of Spain) successively received the duchy of Parma (1732) and the kingdom of Naples (1734), and his brother Philip acquired Parma in 1748.

Insofar as Philip had a foreign policy independent of the ambitions of his wife, it was determined by his unswerving determination to safeguard his claim as a Bourbon prince to the throne of France. His father had died in 1711 and his elder brother in 1712 so that the only person who stood between Philip and Versailles was his nephew Louis XV, a sickly child who seemed most unlikely to grow to manhood or ever produce an heir. In January 1724 Philip abdicated from the Spanish throne. His decision may have been partly inspired by his desire to secure the throne of France, but his eldest son Luis, who succeeded him, died in August 1724 and Philip was then prevailed upon by Isabella and by the French ambassador, the comte de Tessé, to resume the Spanish crown. At home Philip's reign was characterized by an increase in centralization and considerable financial reforms which were largely the work of the French advisers, particularly Jean Orry, who had been sent by Louis XIV to help the king at the beginning of his reign. The reforms were inspired by the example of Louis XIV, but they were the work of such men as Orry, Alberoni, and José Patiño and owed little or nothing to Philip V.

Apart from his almost morbid devotion to religion, Philip's two chief interests were hunting and music. In later life he came to appreciate the singing of the famous Carlo Farinelli. Philip insisted on Farinelli's singing the same few songs night after night and would himself shout them in a tuneless voice. Even as early as 1722, when the duc de Saint-Simon visited Spain, Philip showed signs of having deteriorated seriously from the handsome young prince who had been nicknamed by his subjects *El Animoso.* Already his gait was shambling, his clothes old and shabby and during an audience he stood with his mouth open. For months during the 1730s Philip suffered from some kind of melancholia. He feared he was being poisoned; would wear only a chemise belonging to his wife; would not have his hair or beard cut; and sometimes lay in bed for long periods without speaking. News of the possibility of a military expedition or a rumour that the king of France was ill would revive him from these states of insanity, but during the latter part of his reign his wife largely controlled public business. Philip died at Madrid on July 9, 1746.

PHILIP (*c.* 20 B.C.–A.D. 34), the tetrarch, son of Herod (*q.v.*) the Great by a Jerusalem Jewess, Cleopatra, was brought up at Rome. By his father's final will, as ratified by Augustus, Philip became tetrarch of the northeastern appanages of Herod's realm; Ituraea and Trachonitis (Luke iii, 1), in southern Lebanon and modern Syria, to the east of the Sea of Galilee. He was a model ruler, of whom almost nothing is known, and ruled for 37 years (3 B.C.–A.D. 34). He went on official tours with a modest staff, taking with him a portable judgment seat to administer justice on the spot. He enlarged the temple precinct of Paneas, above the source of the Jordan, and called his new city Caesarea Philippi. He was married to a niece, Salome, daughter of Herodias. It is she, not her blameless husband, who is remembered to this day as

having been the immediate cause of the execution of John the Baptist (Matt. xiv, 3–11; Mark vi, 22–28).

See S. Perowne, *The Later Herods* (1958). (S. H. P.)

PHILIP THE BOLD (1342–1404), duke of Burgundy from 1364, was born on Jan. 17, 1342, the fourth and youngest son of John II, king of France. He fought at his father's side at Poitiers (1356) and shared his subsequent captivity in England. He was granted the duchy of Touraine in October 1360 and was appointed king's lieutenant in Champagne and Burgundy in June 1363. His father's grant of the duchy of Burgundy to him (September 1363) did not become effective till June 1364, when his brother, the new king Charles V, confirmed it. Philip had renounced Touraine, but retained his appointment as king's lieutenant till 1367.

Philip and Charles V supported each other's policies. Philip helped Charles to suppress marauding bands in Burgundy and later took part in the campaigns against the English. His marriage (June 1369) to Margaret of Flanders, widow of the former duke of Burgundy, Philip of Rouvre (d. 1361), was arranged by Charles to prevent Margaret's marrying an English prince.

Philip supported his father-in-law, Louis of Male, count of Flanders, against the rebellious Flemings (*see* below); and when Louis died (January 1384) Philip and his wife inherited Flanders, Artois, Rethel, Nevers, Franche-Comté, and some lands in Champagne. Having won the submission of the Flemings in 1385, Philip in 1386 arranged to separate the administration of his northern territories from that of his southern, setting up both at Lille and at Dijon a *chambre de conseil* (chamber of government) and a *chambre des comptes* (exchequer). In order to induce his wife's aunt, the childless Joan (Johanna), duchess of Brabant, to adopt as her heir his second son, Anthony of Rethel, he had to oppose the claims to Brabant of the house of Luxembourg, to which Joan's husband had belonged. For this purpose he allied himself with the counts of Holland of the house of Bavaria (Wittelsbach): in 1385 his eldest son John (*see* JOHN the Fearless, duke of Burgundy) was married to Margaret of Bavaria, while Margaret's brother, the future William VI of Holland, was married to Philip's daughter Margaret. For John and Margaret he bought the countship of Charolais in 1390; and his transactions with Joan of Brabant finally secured the duchy of Limburg for Anthony in 1396 and the eventual succession to Brabant on Joan's death in 1406. (*See* NETHERLANDS, THE: *History*.)

Meanwhile Philip and his brothers had shared the government of France and the spoils of power there during the minority (1380–88) of their nephew, King Charles VI. In furtherance of his own aims Philip had taken the king and the royal army to Flanders in support of Louis of Male in 1382, when they won the great Battle of Roosebeke and laid siege to Ghent. He had also arranged the king's marriage (July 1385) to Isabella of Bavaria and involved him (August 1388) in an arduous and inglorious campaign on behalf of Joan of Brabant against William of Gelre. In November 1388 Charles terminated the regency of his uncles; but in 1392, when Charles became insane, Philip regained his preeminence in France. He could thus impose his own policies on the French government: alliance with England (1396); and the withdrawal (1398) of support for the Avignon pope Benedict XIII, since Philip's Flemish subjects adhered to the Roman, Boniface IX. On various pretexts, moreover, he extracted large sums of money from the royal treasury, thus coming into conflict with Charles VI's brother Louis, duc d'Orléans (*q.v.*), who favoured a different policy and wanted any diversion of royal funds to be to his own benefit.

Philip was a patron of the arts. He collected illuminated books and manuscripts and commissioned from Christine de Pisan the *Livre des fais et bonnes moeurs du sage roy Charles V* and from Gace de La Bigne his poem on hunting. He ordered jewelry from the goldsmiths and precious cloth from the merchants (especially from Dino Rapondi of Lucca) and encouraged painters, for instance Jean Malouel. To shelter his tomb, at Dijon, he built the Chartreuse de Champmol, which was adorned by the sculptures of Jean de Marville and of Claus Sluter (*q.v.*). He fell heavily into debt, however, chiefly through financing his son John's crusade against the Ottoman Turks (1396) and then paying John's ransom of 200,000 gold ducats. Consequently his widow renounced her right of succession and the obligations that it entailed after Philip's death, which took place at Halle, in Brabant, on April 27, 1404.

BIBLIOGRAPHY.—O. Cartellieri, *Geschichte der Herzöge von Burgund, 1363–1477*, vol. i: *Philipp der Kühne* (1910); H. David, *Philippe le Hardi au début du XIV^e siècle* (1945); J. Calmette, *Les Grands Ducs de Bourgogne* (1949); R. Vaughan, *Philip the Bold* (1962). (J. B. R.)

PHILIP THE GOOD (1396–1467), duke of Burgundy from 1419, was born at Dijon on July 31, 1396, the son of John (*q.v.*) the Fearless and Margaret of Bavaria. He bore the title comte de Charolais during his father's lifetime and was governing Flanders when John was assassinated (Sept. 10, 1419). Succeeding to the duchy and to his father's other titles, Philip decided, not without hesitation, to recognize Henry V of England as heir to the French crown (*see* HUNDRED YEARS' WAR), so as to compel the queen of France, Isabella of Bavaria, to disinherit the dauphin (later Charles VII of France), whom he held to be answerable for the murder of John the Fearless. He campaigned against the dauphin's troops in Picardy (receiving knighthood at the Battle of St. Riquier) and on the frontiers of Burgundy. Even so, John, duke of Bedford, regent of France for the new English king Henry VI, had to marry Philip's sister Anne (1423) and to grant Auxerre, Mâcon, and Bar-sur-Seine to him (1424) in order to retain his loyalty; and when Philip withdrew his troops from the siege of Orléans (1429), Bedford had to promise Champagne and Brie to him as well before he would take up arms against Joan of Arc (1430).

After his campaign of 1433 against Charles VII's troops in Burgundy, Philip consented to act as mediator between English and French at the Congress of Arras (summer 1435). When his mediation proved fruitless, he concluded his own Treaty of Arras with the French (Sept. 21, 1435). By this he acknowledged Charles VII as king of France, accepting his disavowal of the murder of John the Fearless, but exacting from him not only confirmation of the grants made by Bedford in 1424 but also new concessions in Burgundy and chiefly in Picardy: namely the countship of Ponthieu, Montdidier, Roye, Péronne, and the "Somme towns," that is, all the strongholds, lands, and lordships of the royal domain on the Somme River and beyond it in the direction of the Low Countries, with the proviso that the French king might buy these Somme towns back for 400,000 gold crowns.

At war against the English, Philip helped the French armies to recover Paris (1436) and conducted an unsuccessful siege of Calais; but in 1440 he signed a truce with the English. By paying the ransom for Charles, duc d'Orléans, he put an end to the long-standing enmity between the houses of Burgundy and of Orléans.

Meanwhile Philip had been augmenting his territorial power in the Netherlands. He purchased the rights to the countship of Namur in 1421 and came into possession of it in 1429; he obtained the administration of Holland, Zeeland, and Hainaut from the countess Jacoba (*q.v.*) in 1428, after some years of conflict; he inherited Brabant and Limburg in 1430; and after transactions with Elizabeth of Görlitz he was able to occupy Luxembourg in 1443. It only remained for him to subdue the Flemish communes, and by his victory in the Battle of Gavere (1453) he forced Ghent to submit. The ecclesiastical principalities of the Netherlands had to accept his nominees as bishops; *e.g.*, David, one of his numerous bastards, bishop of Utrecht from 1455. Whereas the Holy Roman emperor Sigismund had objected, in vain, to Philip's aggrandizement, the future emperor Frederick III suggested in 1447 that Philip's possessions should be erected into a kingdom. Philip, however, rejected Frederick's terms.

With the help of Nicolas Rolin, his chancellor from 1422 to 1457, Philip reorganized the administration of his territories. He also founded the Order of the Golden Fleece on the occasion of his marriage, in 1430, to his third wife, Isabella of Portugal. His first marriage (1409) had been to Charles VI's daughter Michelle of France (d. 1422), his second (1424) to Bonne of Artois (d. 1425).

Philip's great project, from 1432, was a crusade against the Turks. From 1441 to 1445 he maintained a fleet in the Mediterranean and in the Black Sea. After the fall of Constantinople (1453) he took the cross himself at his splendid "Banquet of the Pheasant," in Lille, on Feb. 17, 1454. He made contacts with the princes of eastern Europe who were already in league against the Turks

and tried to induce France and Germany to collaborate. Finally he organized an expedition and dispatched its first contingent in 1464, but it went no farther than Marseilles.

By this time Philip's relations with France were strained again. In 1456, when the dauphin Louis (*see* LOUIS XI, king of France) appeared at his court as a refugee, Philip granted him asylum, and Charles VII never forgave this. On Charles VII's death (1461) Philip escorted Louis back to France as king; but Louis then began to build up a faction of his own among members of Philip's entourage. One of these, Antoine de Croy, persuaded the duke to allow Louis to redeem the Somme towns (August 1463), in accordance with the treaty of 1435. Then Philip's son Charles (*see* CHARLES the Bold, duke of Burgundy), who had been on bad terms with his father since 1457, got rid of Croy by a *coup d'état* (February–March 1465); and in April 1465 Philip handed the government over to Charles, with the title of lieutenant general. Philip died at Bruges, in Flanders, on June 15, 1467.

Philip was renowned as a patron of artists—painters, miniaturists, sculptors, musicians, and writers. His court was magnificent; and jousts and banquets attracted knights from every part of Europe. His lands enjoyed great prosperity under him. *See* also references under "Philip the Good" in the Index.

PHILIP THE MAGNANIMOUS (1504–1567), landgrave of Hesse from 1509, an outstanding figure among the German-Protestant princes of the Reformation, was born at Marburg on Nov. 13, 1504, the son of the shrewd and energetic landgrave William II. As he was only five years old when his father died (1509), his mother, Anna of Mecklenburg, became regent for him. Her passionate and forceful character led to conflict between the government and the estates of Hesse till in 1518 the Holy Roman emperor Maximilian I pronounced Philip to be of age to rule.

Philip never forgot the bitter experience of his youth, when, in the struggle against Franz von Sickingen (*q.v.*), a part of the Hessian nobility, out of self-interest, went over to the enemy's side. For himself he retained his parents' valued counselors, mostly of bourgeois stock, who worked for the political rehabilitation of his shattered territory and imbued him with their own single-minded devotion to its welfare. Throughout his reign he thought always in terms of the territorial state; and this consideration made him the defender of the Middle German principalities in the Peasants' War (1525) and subsequently determined his relations with the imperial House of Habsburg. He ruled in a spirit of enlightened absolutism.

In 1524, when Luther's doctrine had already won some adherents at his court and elsewhere in his dominions, Philip personally went over to the Reformation; but he began to apply it to his territory only when the imperial Diet of Speyer had apparently made such action legal (1526). He then convened a "synod"—half Hessian church council and half an assembly of the estates—at Homberg and had the religious question publicly debated. His theologians, among whom the former Franciscan, Lambert of Avignon, was especially influential, consequently drew up the *Reformatio ecclesiarum Hassiae*, which included many elements of South German and Swiss Zwinglian thought; but since Luther and Melanchthon rejected this scheme, Philip in 1527 adopted instead a program modeled on that of the Reformation in electoral Saxony. Together with the secularization of monastic property, the Hessian Reformation was characterized by the systematic way in which the new ecclesiastical order was implanted: for instance, the first Protestant university was established at Marburg in 1527.

Though he henceforth determined the religion of his territory, Philip, unlike many other German princes, yet respected freedom of conscience insofar as he allowed his subjects to emigrate. When Anabaptism spread over Germany, he saw in it a genuine crisis in the relationship between the faithful and their church. While numerous princes dealt harshly with the Anabaptists, he had some success in converting the dissidents by methods of gentle persuasion, in which he had the valuable support of Martin Bucer from Strasbourg; and the rite of confirmation, introduced in Hesse (December 1538) with a view to solving the Anabaptist problem, set the pattern for all other Protestant churches. Philip's humane treatment both of the peasants after their defeat in 1525 and of the outlawed Anabaptists contrasts very favourably with the conduct of most other German princes.

Philip's change of religion compromised his political position. It was for that reason that he and the elector of Saxony, John the Steadfast, in 1526 formed the defensive alliance known as the Gotha-Torgau League, which in 1531 grew into the League of Schmalkalden. For 20 years this Hessian-Saxon alliance formed the axis of the Protestant concert and decisively influenced the course of German history; and during this period the versatile and infectiously energetic Philip was the leader of political Protestantism. Yet the Pack affair of 1528 (*see* PACK, OTTO VON) exposed in him a credulity which detracted from his statesmanship, while the disadvantages of mixing religious motives with princely interests also became apparent. Politically he recognized the danger of splitting the Reformation between North German Lutherans and South German Zwinglians; and so, without regard for the dogmatic points at issue, he tried in vain to reconcile Luther and Zwingli at the Colloquy of Marburg (*q.v.*) in 1529. The far-reaching hopes that he and Zwingli entertained of a European alliance against the Catholic emperor Charles V came to nothing. Philip brought his fame to its zenith through the successful campaign of 1534 by which he restored the exiled Ulrich of Württemberg to his duchy and opened Württemberg to Protestantism.

Philip forfeited his leading role in Protestantism and brought the Reformers into disrepute by entering, in 1540, into a secondary marriage with Margarete von der Saale, though his lawful wife, Christine of Saxony, whom he had married in 1523, was still alive. Since the emperor Charles V was already determined to solve the religious question by force of arms, hostilities could not long be postponed; and despite a temporary *rapprochement* between the rivals, the Schmalkaldic War broke out in 1546. After an inglorious campaign by the league in southern Germany, Philip's ally, the elector John Frederick I of Saxony, was taken prisoner at Mühlberg (1547), and Philip then made his submission to the emperor. To his bitter dismay, he too was taken into captivity. His attempt to win freedom by accepting Charles V's Augsburg Interim was thwarted by his subjects' refusal to accept it; but the shallowness of Philip's religious insight and his readiness to abandon his spiritual commitments were made clear. Not until 1552 were Philip and John Frederick set free, when the alliance of Philip's son-in-law Maurice (*q.v.*) of Saxony, Philip's eldest son the landgrave William IV, and other German princes with Henry II of France had forced Charles to make the Peace of Passau.

Restored to Hesse, Philip tried thereafter to maintain the peace of Germany. Prematurely aged and saddened by the quarrel between his two families of descendants, he devoted his efforts to rebuilding the prosperity of Hesse again. If he took any further part in high politics, it was to promote the unity of Protestantism and to help those of the faith who were persecuted in France and in the Netherlands. By the time of his death, which took place at Kassel on March 31, 1567, he was already known to his contemporaries as Philip the Magnanimous (*der Grossmütige*).

PHILIP (Indian name METACOMET) (*c.* 1639–1676), sachem of the Wampanoag Indians and leader of the worst Indian war in New England's history, was the son of Massasoit and the brother of Alexander (Wamsutta). Both Alexander, who succeeded his father (Massasoit) in 1661, and Philip, who became sachem after Alexander's death in 1662, pledged to keep the peace established by Massasoit with the English, but the pledge became more difficult to fulfill as the differences between the Indians and the English became a struggle for survival between two mutually antagonistic civilizations. The proud, ambitious Philip was embittered by the

humiliations to which he, his brother, and his people were subjected, and there is circumstantial evidence that he had a plot under way in 1674–75 to clear the English from Indian lands. In June 1675, when three of Philip's warriors were executed for the murder of an informer, John Sassamon, Philip could no longer hold his young braves in check, and war came before any well-planned or coordinated campaign had been worked out. The fact that this war was, in proportion to population, one of the most costly in lives ever fought in North America was more the result of colonial inefficiency than Indian genius in battle. Philip was not the great leader he was once assumed to be. King Philip's War bears his name because he started it and became a symbol of the struggle, but he was never in command and actually had no major part in the battles after the summer of 1675. He was killed Aug. 12, 1676.

PHILIP, JOHN (1775–1851), Scottish missionary, who successfully defended the rights of the Hottentots against exploitation by the settlers in South Africa, was born at Kirkcaldy, Fife, on April 14, 1775, and was minister to the Great George Street Congregational Church, Aberdeen, 1804–18. During this period he became a director of the London Missionary Society, which in 1818 appointed him a member of a commission sent to investigate its affairs in South Africa. What he saw there of the disabilities and sufferings of the Hottentots, many of whom were virtually slaves to the British and Dutch settlers, determined him to seek justice for them.

By correspondence with influential friends, among them William Wilberforce, by his own speeches during his visit to Great Britain in 1826 and by his book *Researches in South Africa* (1828), Philip did much to rouse opinion about the Hottentot question. He secured the enactment (1829) by the British government of Ordinance 50 embodying the principle that "the same freedom and protection be given to all the natives of South Africa as are enjoyed by all other persons residing at the Cape."

Philip's activities on behalf of the natives brought him great unpopularity in Cape Colony, especially among those who, when earlier compeled by law to emancipate their slaves, had retained a few Hottentots and believed in their right to control and direct them. Even after his death at Hankey on Aug. 27, 1851, his name was execrated by many white people in South Africa, but historians have vindicated his memory. *See* also CAPE OF GOOD HOPE: *History*.

PHILIPON, CHARLES (1806–1862), French journalist, caricaturist and lithographer who raised caricature from the level of a print-seller's venture to that of a regular feature in journalism. Born at Lyons, April 19, 1806, he settled in Paris in 1823, took to lithography and began to draw caricatures for a living. He was an excellent draftsman with a fertile and irrepressible sense of satire. Moreover, he had vigorous political opinions, an enterprising spirit and boundless energy. Among the projects that overflowed from his active mind was an ambition to found a paper. This was realized in 1830 when he published a journal of political satire, *La Caricature*. Its career was brief and turbulent; after an avalanche of legal actions, it was suppressed in 1834. Meanwhile, in 1832, Philipon had produced a daily paper (with a new drawing every day) called *Le Charivari* which, ten years later, was to become godfather to *Punch* or *The London Charivari*. In 1838 *La Caricature* made a cautious reappearance under the title of *La Caricature Provisoire* but its success was such that, before long, the adjective *Provisoire* was discarded. His next publication of importance, *Le Journal pour Rire* (later *Le Journal Amusant*) appeared in 1849 in the form of large newspaper sheets filled with woodcuts. Besides these journals, Philipon issued many occasional publications, such as *Le Musée Philipon*, *Le Robert Macaire*, *Les Physiologies* and numerous political brochures.

As an artist, his best-known invention was a drawing which depicted the gradual transformation of Louis Philippe into the shape of a pear. *La Poire* became the common symbol of the king and all Philipon's artists used it in their caricatures. They were a notable group: he was able to attract and inspire the best talents in France. Honoré Daumier and Gustave Doré were the most famous but, there were also Paul Gavarni, Grandville (J. I. I. Gérard), Henri Monnier, Auguste Raffet and Charles Joseph Traviès de Villers. For one man, his achievement was considerable; his effect on caricature in France and other countries was decisive, as was his influence on the development of lithography as an artistic and commercial medium.

Philipon died in Paris, Jan. 25, 1862.

See Champfleury (Jules Fleury), *Histoire de la Caricature Moderne* (1865); Edwin de Turck Bechtel, *Freedom of the Press and L'Association Mensuelle: Philipon Versus Louis Philippe* (1952). (F. W. W.-S.)

PHILIPPA OF HAINAUT (*c.* 1314–1369), queen consort of the English king Edward III, was the daughter of William I the Good, count of Hainaut and (as William III) count of Holland, by his wife Jeanne de Valois, granddaughter of Philip III of France. Philippa's marriage was arranged in 1326 by Edward's mother, Queen Isabella, who was in Hainaut with her son gathering forces for the rebellion against Edward II. Philippa was married by proxy at Valenciennes in Oct. 1327; she crossed to England in December, joined Edward at York, and was remarried there on Jan. 24, 1328. She was crowned at Westminster a few weeks later. She accompanied Edward on his Scottish campaign in 1333 and was with him in Flanders, at the beginning of the Hundred Years' War, from 1338 to 1340. In 1348 she joined him at the siege of Calais.

Philippa was constantly in debt, but this was not necessarily due to culpable extravagance. At her marriage only 1,000 marks (£666 13*s.* 4*d.*) out of a promised dower of £3,000 were assigned for her expenses. In 1330, however, she was granted several estates and in Dec. 1330 she received, among other payments, £1,000 from the customs at Hull. But in 1333 Edward had to disburse £2,000 toward her debts and in Feb. 1363 the revenues from all her lands were reserved for six years until her debts should be paid. Her household was then merged with that of the king.

Philippa, described by contemporaries as a "full noble and good woman," was loved for her gentleness and compassion. When a stand collapsed at a tournament in Cheapside (London) in 1331, injuring some of her retinue, she saved the carpenters from punishment. There is no serious reason to doubt the famous story of her intercession for the lives of the burghers of Calais, although it is not mentioned by all the chroniclers. Unlike certain earlier foreign queens, Philippa did not swamp the English court with her compatriots. The most notable Hainauters of whom she was patron were Sir Walter de Manny, who arrived in her retinue and by 1372 held land in 16 English counties, and Jean Froissart, who acted as her secretary from 1361 until her death. She supported the Flemish weavers who settled at Norwich, visiting them in 1340, 1342, and 1344. Queen's college, Oxford, founded by her chaplain, Robert of Eglesfield, was named after her, as were the castle and town of Queenborough in Sheppey (Kent), built by William of Wykeham.

Philippa bore her husband seven sons and five daughters (*see* EDWARD III). She died at Windsor on Aug. 15, 1369.

See A. Strickland, *Lives of the Queens of England*, rev. ed. (1878).

PHILIPPE, CHARLES LOUIS (1874–1909), French writer of novels which describe from personal experience the sufferings of the poor. Born at Cérilly (Allier), on Aug. 4, 1874, the son of a shoemaker, he was ambitious to become an army officer, but was refused entry to the École Polytechnique in 1894 because of his puny physique and finally found employment in the Paris municipal service as a shop inspector. He died in Paris of typhoid on Dec. 21, 1909.

His novels either describe the dregs of Parisian society or are set in his native province. Of the first group, the most notable is *Bubu de Montparnasse* (1901; English translation 1952), which tells the story of a young prostitute's relationship with her procurer, and with a young intellectual who tries to save her. The novels of rural poverty include *La Mère et l'enfant* (1900), in which he tenderly recalls his own childhood; *Le Père perdrix* (1902; title page 1903), the story of an old blacksmith, reduced by illness

to indigence, and of a young engineer who loses his job because of his independence of outlook; and the unfinished *Charles Blanchard* (1913), a moving evocation of the unhappy childhood of his father.

Philippe's novels are distinguished by acute pity for the social outcast, and by his power to depict tenderly, yet with realistic precision, the sufferings of the poor in their struggle against cold and hunger. Although his style can be cloying, at its best it conveys emotional intensity by its simplicity and sincerity.

See J. de Fourchambault, *C.-L. Philippe: le bon sujet* (1943).
(Ja. La.)

PHILIPPEVILLE (Skikda since Algerian independence), a town and Mediterranean seaport of northeastern Algeria in Constantine *départements*, lies on the Gulf of Stora, about 55 mi. NNE of Constantine by rail and road. Pop. (1960) 80,281. Formerly the population was predominantly European, partly of Italian and Maltese origin, but during the Algerian War there was an influx of Muslim refugees and subsequently an exodus of Europeans.

Founded by the French in 1838 to serve as the port of Constantine, Philippeville is rectilinear in plan and occupies the site of ancient Rusicade, which was the port of Cirta, as Constantine was called until the 4th century. It lies near the mouth of the Safsaf River, escaping the humidity of the alluvial plain by its situation on a saddle between two hills. The road and the railway to Constantine follow the course of the former Roman road. The Safsaf Valley is rich in vines, citrus fruit trees, and early vegetables; Philippeville exports its products as well as those of the upper plains of the Constantine region (chiefly cereals and the products of sheep raising), dates from the oases of the Biskra region, and iron pyrites from the surrounding district. It imports combustibles and construction materials, and also a wide variety of manufactures and sugar and coffee, which are redistributed through Constantine to the whole of eastern Algeria. There is considerable passenger traffic through the port, which, with the village of Stora, is a centre for sardine fishing and canning.
(J.-J. Ds.)

PHILIPPI (modern Greek Filippoi in the *nomos* of Drama), a city of ancient Macedonia, on a steep hill near the Gangites (modern Angitis) River, overlooking an extensive coastal plain on the highway between Neapolis (Kavalla) and Thessalonica (Salonika). Originally a Thasian settlement called Crenides ("fountains"), it was fortified by Philip II of Macedonia in 356 B.C., to control the neighbouring gold mines.

In 42 B.C. Philippi was the site of the decisive battle in which Mark Antony and Octavian (later the emperor Augustus) defeated Brutus and Cassius. The latter, whose forces roughly equaled those of their opponents, lay astride the Via Egnatia to the west of Philippi, their position being partly protected by a marsh. Antony made a successful attack on the camp of Cassius, who, not knowing that Brutus' forces had successfully assailed Octavian's camp, committed suicide. About three weeks later, on Oct. 23, Brutus against his better judgment fought a second action in which he was routed; despairing of restoring the republican cause, he too took his own life.

After the battle a colony for Roman veterans was started at Philippi, and this was later reinforced by Augustus (according to Dio Cassius in 30 B.C. for supporters of Antony who had been dispossessed of their lands in Italy; former members of the praetorian cohorts also shared in the settlement). The first colony (ignored by ancient writers) is attested by coins with the legend *A(ntonii) I(ussu)* ("by order of Antony") *C(olonia) V(ictrix) P(hilippensium)*. Philippi was visited on his second and third missionary journeys by St. Paul, whose Epistle to the Philippians was written to the Christian converts there. The site has many ruins, especially of the imperial epoch, including the huge monument of the Roman soldier Gaius Vibius (known locally as "the manger of Bucephalus").

See S. Casson, *Macedonia, Thrace and Illyria*, part i (1926); P. Collart, *Philippes* (1937). (H. H. So.)

PHILIPPIANS, EPISTLE TO THE, a book of the New Testament, written by St. Paul to thank the church at Philippi, in Macedonia, for the financial assistance it had sent him when he was in prison, apparently facing the prospect of execution but still not without hope of release (1:19–26; 2:24). Its authenticity, doubted in the 19th century, is now almost universally accepted.

The Philippians seem to have been conscious of their position as the first European congregation of Paul, who crossed from Asia Minor into Macedonia after a special revelation (Acts 16:6–12). Paul himself looks back on the conversion of the Philippians as "the beginning of the gospel" (4:15). The Philippians alone among his churches continued to send him money (4:16; II Cor. 11:8–9), and they promised support for his collection among the gentile churches for the mother church of Jerusalem (II Cor. 8:1 ff.). For a long time they had sent nothing, but hearing of Paul's imprisonment they sent relief by the hand of one Epaphroditus, who, discovering his needy state and the insufficiency of the amount sent, laboured to earn more and in so doing fell ill. On recovery Epaphroditus became the bearer of Paul's letter of thanks to the church; the "bishops and deacons" singled out in the address (1:1) were perhaps responsible for the church chest. The Epistle is an intensely personal document, perhaps the most attractive of Paul's writings. At the same time there are undercurrents of passionate debate. His thanks are combined with admonition, and there are reverberations of harsh controversy centring in Paul himself. The Epistle's tranquillity is far from effortless, and the sunlight shines through lowering storm clouds. That Paul's rejoicing is achieved under strain is shown by the left-handed praise for the evangelistic labours of his rivals (1:15–17).

Contents.—The book may be outlined as follows:

1:1–11	Paul thanks the Philippians for their support in his imprisonment
1:12–18	This imprisonment, however, has been providentially overruled
1:19–26	Soon he hopes to visit the Philippians
1:27–2:18	let them keep unity by humility and love
2:19–30	they should be ready to welcome Timothy and Epaphroditus
3	they should beware of agitators
4	let them continue in glad dependence on God in mutual harmony

Literary Unity.—The problem of literary unity is raised by the sudden attack (3:2 ff.) on some who teach that gentile Christians need to be circumcised to attain perfection. The identity of these teachers is problematic; they may be members of the orthodox synagogue, or Jewish Christians, or Judaizing "gnostics" of uncertain morality (*cf.* 3:19). The change of mood at 3:2 has led to the conjecture that at this point there has been inserted into the letter to Philippi a fragment of another Pauline letter of unknown date and destination. Those who hold this view, however, disagree about the point where the insertion ends (3:19; 4:1, 4, 20 have all had advocates, 4:1 being supported by a majority). The probability of the conjecture is bound up with the view taken of the similar phenomena of sudden changes of mood in I and II Corinthians, which have also led to speculation that these Epistles (especially II Corinthians) consist of diverse fragments casually united perhaps by an unknown person who in about the year 95 is supposed to have published the Pauline corpus. Admittedly, the case for regarding either of the Corinthian Epistles as other than a literary unity falls far short of demonstration, and the case for so regarding Philippians is much weaker.

Place of Writing.—Traditionally the place is generally understood to be Rome, where Paul is known to have been imprisoned and executed. This hypothesis receives powerful support from the references to "the whole praetorian guard" (or "the whole praetorium") in 1:13 and to Christians in "Caesar's household" in 4:22. These phrases, however, do not compel the conclusion that the Epistle was written in Rome, and some 20th-century scholars have dated the letter many years earlier and ascribed it either to the imprisonment at Caesarea in "Herod's praetorium" (Acts 23:23–35) or to a hypothetical imprisonment at Ephesus for which there is no evidence. In favour of Ephesus it is argued, on the one hand, that the hypothesis makes it easier to regard as authentic some parts of the Pastoral Epistles to Timothy and Titus, and on the other hand that Epaphroditus' journey from Philippi to Rome would require seven weeks, whereas he could have reached Ephesus in ten days. (It is a point against the Caesarean hypothesis that

the overland journey to Caesarea would have taken much longer than that to Rome; in the summer a sea voyage of about a month would be necessary.) If Paul's prison was not at Rome, 1:13 may refer to a detachment of the praetorian guard in the provinces. Asia was a senatorial province, but "Caesar's household" might mean the staff who managed imperial estates there. Moreover, Phil. 1:1 and 2:19 ff. show that Timothy is with Paul; Timothy's presence at Ephesus is attested in Acts 19:22, but that he was ever in Rome is mere conjecture. Accordingly, the Ephesian hypothesis can be made plausible. However, the traditional view that the Epistle was written in Rome cannot be called implausible, and it remains the more probable opinion.

Influence.—Theologically, the most influential passages in the Epistle are: (1) The Christological hymn of the humiliation of the Son of God and his exaltation on the ground of his obedience (2:5–11; this has been regarded, without sufficient evidence, as a pre-Pauline hymn). The doctrine of the person of Christ here is remarkable for its use of language closely parallel to that used by Hellenistic writers about divine heroes such as Heracles, who, though the son of Zeus and Alcmene, was elevated to divine honours on account of his virtue. The passage influenced the theology of Theodore of Mopsuestia and the anti-Apollinarian school of Antioch in the 4th and 5th centuries. In modern times the statement that the Son "emptied himself" has given the impetus to "kenotic" Christology; *i.e.*, the doctrine that in the incarnation the Son of God set aside his distinctively divine attributes of omniscience, omnipotence and omnipresence. (2) The exhortation (2:12–13) "Work out your own salvation . . . for God is at work in you," which has been appealed to on both sides in the controversy concerning grace and free will. (3) The mystical ideal of never-ceasing advance in the apprehension of Christ, which is also apprehension by Christ (3:8–16). The passage is perhaps the most important single statement in Paul's Epistles of his doctrine of sanctification. *See* also BIBLE; PAUL, SAINT.

(HY. C.)

PHILIPPICUS BARDANES (VARDAN) (d. after 713), Byzantine emperor from 711 to 713, was the son of the patrician Nicephorus of Pergamum. His Armenian name may be derived from his mother. He was banished to Cephallenia by Tiberius III Apsimar, but recalled by Justinian II who sent him to destroy Cherson (Tauric Chersonese, in the Crimea), which was in revolt. He revolted against Justinian, making common cause with Cherson, and was proclaimed emperor under the name of Philippicus. He sailed to Constantinople, gained the throne, and had Justinian and his family killed. Philippicus was a Monothelite, and though he roused the opposition of the orthodox and of Rome he was not without supporters. His extravagance ill-fitted him to organize the imperial defenses against the Bulgars, who plundered up to the city walls, or against the Arabs on the eastern frontier. Military opposition brought about his downfall in 713, when he was deposed and blinded. His chief secretary, Artemius, mainly at the instigation of the senate and people, was hurriedly crowned as Anastasius II.

See J. B. Bury, *Later Roman Empire,* vol. 2 (1889); E. W. Brooks in *Cambridge Medieval History,* vol. 2, ch. 13 (1913).

(J. M. HY.)

PHILIPPINES, REPUBLIC OF THE (REPÚBLICA DE FILIPINAS, REPUBLIKA NG PILIPINAS), an archipelago named after Philip II of Spain, of approximately 7,100 islands, about 500 mi. off the southeast coast of Asia, lying between lat. 4° 23′ and 21° 25′ N. and long. 116° and 126° 30′ E. It is bounded on the west and north by the stormy China sea, on the east by the Pacific ocean and on the south by the Celebes sea and the coastal waters of Borneo. The islands extend north and south about 1,152 mi. (1,855 km.) and east and west about 688 mi. (1,108 km.), their shape, if bounded by straight lines, being about that of an isosceles triangle and their area 115,707 sq.mi. (299,682 sq.km.). The northernmost island, Y'Ami, is 65 mi. S.E. of Formosa, while the southernmost, Saluag, is 30 mi. E. of Borneo. Only 462 of the islands have an area of 1 sq.mi. or more. Eleven have areas of more than 1,000 sq.mi.—Luzon, the most northerly of the large islands, 40,420 sq.mi.; Mindanao, the most southerly, 36,537 sq.mi.; Samar, 5,050 sq.mi.; Negros, 4,905 sq.mi.; Palawan, 4,550 sq.mi.; Panay, 4,446 sq.mi.; Mindoro, 3,759 sq.mi.; Leyte, 2,785 sq.mi.; Cebu, 1,703 sq.mi.; Bohol, 1,575 sq.mi.; and Masbate, 1,262 sq.mi.

In addition to the large islands and those with distinct names are various groups, among which may be noted the Babuyanes and Batanes, north of Luzon; the Visayas (or Bisayas), between Luzon and Mindanao; the Cagayan and the Calamian groups, respectively east and north of Palawan; and the Sulu archipelago of 448 islands, the chief of which is Jolo.

Additional information on the Philippines can be found in the articles on the individual islands, provinces and major cities.

I. PHYSICAL GEOGRAPHY

1. Physical Features.—The irregular configuration of the archipelago, the coast line of more than 21,500 mi. (34,800 km.), the great extent of mountainous country with the mountains lying close to the sea in many places, the narrow and interrupted coastal plains, the generally northward trend of the river systems and the lakes comprise the salient physical features of the Philippines. The islands have volcanic, coral and all principal rock formations. The mountain ranges for the most part run in the general direction of the main axes of the islands. The Cordillera Central of Luzon, running north to the Pacific ocean from the northern boundary of the central plain, is the most prominent chain. It consists of two, and in places three, parallel ranges, each of which averages 5,900 ft. (1,800 m.) in height. The narrow Ilocos or Malaya range, lying close along the narrow west coast, rises in places to more than 5,000 ft. The Sierra Madre, fringing the northeast coast, rises to more than 5,000 ft. and is seldom less than 3,500 ft. high; it is largely volcanic. This range and the Cordillera Central coalesce in Nueva Vizcaya forming the Caraballo mountains. North of the latter and between the two ranges is the fertile

Cagayan valley, about 50 mi. wide. In the southwestern part of northern Luzon are the rugged Zambales mountains, which consist of more or less isolated old volcanic stocks.

The central plain of northern Luzon is about 150 by 50 mi. and only about 100 ft. above sea level except near its centre. The greater part of southern Luzon is occupied by isolated volcanoes and irregular masses of hills and mountains. The highest peak is Mayon (7,943 ft.) near Legaspi in Albay province.

Through Palawan (about 15 mi. wide) extends a range with an average height of 4,000 to 5,000 ft. Each of the Visayan islands, except Samar and Bohol, is traversed longitudinally by a single range with occasional spurs. Several peaks in Panay reach an altitude of 6,000 ft. or more. In Negros is Mt. Canlaon, a volcano of 8,035 ft., and other peaks reach an altitude of more than 6,000 ft.

There are several important ranges in Mindanao, the Diuata range along the eastern coast being the most prominent. West of this lies the fertile Agusan valley, 40 or 50 mi. wide. Farther west and southwest is the valley of the Río Grande de Mindanao, the largest river system in the island, and between the lower course of this river system and the southern coast lies a range trending northwest and southeast. On the southern border of the basin of Río Grande de Mindanao river is Mt. Apo (9,691 ft.), the highest peak in the Philippines. Around Lake Lanao are a number of volcanic peaks. A low cordillera extends into Zamboanga province.

PHYSICAL FEATURES OF THE PHILIPPINES

Many of the mountains are covered with dense forests in which are many valuable hardwood timbers. In northern Luzon the principal mountain tree is the pine. In many places where the forests have been burned away their place has been taken by cogon or other coarse grasses. The plains lying amid the mountains—*e.g.*, the central plain of Luzon, the Bikol plain of southeastern Luzon, the Cagayan plain of northern Luzon, the central plain of Panay and the Agusan and Cotabato valleys in Mindanao—have the densest populations of the islands except in Cebu, where the people live mostly on the coastal plain, as the interior is high and rugged. The most important rivers are the Cagayan, Agno, Pampanga, Pasig and Bikol in Luzon and the Río Grande de Mindanao and Agusan in Mindanao. The Cagayan, flowing northward through northern Luzon and draining about one-fourth of the island, is the largest river. This river and the Río Grande de Mindanao and the Agusan are each more than 200 mi. (322 km.) long. The Pasig, flowing through Manila, is commercially important. The largest lake in the archipelago is Laguna de Bay, located south of Manila.

2. Geology.—Mountain building is still in progress, and evidence of the recent vertical movement of various portions of mountain mass can be measured. The archipelago is the crumpled edge of the Asian continental platform. The structure is a complex one, however, for in addition to faulting and folding, volcanic actions of diverse kinds have taken place. Prior to the Tertiary period there seems to have been a period of intense deformation, when some of the schists were formed. Toward the end of the Miocene period, the Vigo and Batan formations were generally folded, in some places being intensively crumpled and faulted. Another less pronounced period of folding occurred in the Pliocene or early Pleistocene period. The islands were subjected to a great uplift during the Pliocene, Pleistocene and Recent periods. A striking similarity exists between the formation in the Philippines and the western coast of America. Practically all rock types are found in the islands, as well as areas of coral limestone.

3. Volcanoes.—The volcanoes are the most conspicuous feature of the landscape, but there is relatively little volcanic activity. All gradations of volcanoes can be seen, from the almost perfect cone of Mayon to old, worn-down volcanic stocks whose present form gives little indication of their origin. The several distinct volcanic areas are that of southwestern Luzon (the provinces of Rizal, Cavite, Laguna, Batangas and a portion of northwestern Quezon); that of southeastern Luzon; the mountain region in Camarines Norte; Negros; Mindanao; Jolo; and a few others. Seismic disturbances are common.

4. Climate.—The archipelago has a decided variety of climate. The general direction of winds is from north to east, October to January; east to southeast, February to April; and southwest, the rest of the year. Typhoons often strike the islands from the east to the southeast, then curve to the north, sometimes crossing the land to the China sea, sometimes only touching the eastern shores. Eighty-five per cent of them affect the islands from Samar to the north while only 15% are felt south of Samar. Often the greatest loss of life and destruction of property are caused not by high-velocity winds but by the concomitant or subsequent torrential rains, which cause floods.

Temperature differences are slight on the lowlands but altitudinal variations are marked. Rainfall variations are important in dividing the archipelago into climatic regions, and many local rainfall patterns exist. The most common rainfall pattern is that having two pronounced seasons, dry in winter and spring, rainy in summer and autumn, with local variation in the length of the dry season and in the total rainfall. This is found in western Luzon and the western Visayas. A second kind of pattern has a marked winter maximum of rain and irregular but short dry seasons during the summer and autumn, with local variations. This is found in eastern Luzon, the eastern Visayas and northern and eastern Mindanao. Southern and western Mindanao have no pronounced seasonal maximum of rain but do have short irregular dry seasons, with local variations.

5. Vegetation.—About 10,000 species of flowering plants and

ferns have been found. The flora is essentially Malaysian, but continental (Himalayan) elements occur in the mountains of northern Luzon, while a few Australian types are found at various altitudes. There is a small percentage of native genera and a high percentage of native species (about 60%). The dominant forest species are usually native. Among the grasses of the grasslands are lalang (cogon) and other coarse grasses. The vegetation of the coastal regions (including the mangrove swamps) is practically identical with that of similar areas throughout the Malay archipelago. Considerably more than half the land area of the islands is covered with forest. Members of the *Lauan* family, known as Philippine mahogany, often comprise a high percentage of the forest. There are many other valuable hardwoods as well as many softwoods. About 1,000 different woods have a commercial value, among which may be noted apitong, camagon, ipil, lauan, *mayapis*, molave, narra, *tangile*, tindalo and yacal. Some timber trees attain a huge size which makes them especially adaptable for tables and other large pieces of furniture. There are many useful kinds of palms, including the coconut palm, from which is obtained food, clothing, fibre for export, coconut oil, copra, building material and other products. Useful bamboos and rattans abound. About 900 species of orchids occur; some of them very rare. Several hundred fibres are known, among them the abacá, from which manila rope is made. The forests also yield gums (including rubber), various fruits, nuts, spices and drugs, oils and other useful substances.

EWING GALLOWAY

CROSS SECTION OF PHILIPPINE VEGETATION ON PANAY

6. Animal Life.—Mammals are scarce, with the exception of shrews, rats, mice and bats. The anteaters are represented by the pangolin. Red or brown deer (*Rusa*) are found in Basilan, Mindanao, Leyte, Samar and the Calamian Islands. The mouse deer or chevrotain (*Tragulus nigricans*) is found in Balabac and Palawan. The timarau (*Bubalus mindorensis*), a small buffalo, is peculiar to Mindoro. Carnivores are represented by mongooses (*Mungos palawanus* and *M. parvus*), the binturong (*Arctictis binturong*), an otter (*Aonyx cinerea*), civet cats (*Viverra* and *Paradoxurus*) and a small wildcat (*Felix minuta*) which is also found in Java. At least 56 species of bats are known, many being peculiar to the Philippines. The flying lemur (*Cynocephalus volans*) and tarsier (*Tarsius*) range from Basilan to southern Luzon. Large fruit bats live in colonies and are sometimes hunted for their flesh and fur. Only one genus of monkey (*Pithecus*) has been found, but it is represented by five species. Five new genera of small mammals (*Celaenomys, Chrotomys, Rhynchomys, Batomys* and *Carpomys*) representing 15 species have been discovered on a small plateau on the top of Mt. Data in northern Luzon, at an altitude of more than 8,000 ft. There are about 760 species of birds which show rather strong relationship to those of Borneo. Reptiles and batrachians also abound.

The marine fauna is one of the most abundant known, more than 1,000 species having been found, at least three-fourths of which are used as food. Sharks and rays are caught for their fins. The fresh-water fish fauna is relatively unimportant. Terrestrial and marine mollusks are abundant, the Philippines having the richest molluscan fauna of any equal area in the world, and many of the shells are of great beauty. Many of the mollusks are edible and of considerable local importance. Pearl oysters abound and the pearls of the Sulu archipelago have an international reputation. The shells of *Placuna placenta* have been used as a substitute for window glass. Land mollusks are found in great variety and are remarkable for their beauty. The best sponges of the southern islands are equal to those of the Mediterranean. Coral beds are numerous. (R. E. He.)

II. THE PEOPLE

The population of the Philippines is composed of a considerable number of cultural and linguistic groups, the result of varied historical relationships and of local specialization. Ancestors of the present-day population came from southeast Asia, either by way of the island chains to the south or directly across the China sea. Chinese from the coastal cities of south China came to trade and remained in Luzon and the Bisayas; Arab and Indian traders added their blood to the Muslim population in the southern islands; later came rulers from Spain and the U.S. At the time of Magellan (1521) the estimated population of the Philippines was about 500,000; since then it has increased over fortyfold. During this period there has been a blending of diverse racial strains, though linguistic differentiation continued until well into the 20th century. Increased mobility and the long period of Spanish and U.S. control, however, brought about considerable cultural uniformity except in the Muslim and pagan areas.

1. Racial Types.—The peoples of the Philippines belong to the Malay race which is a subdivision of the great Mongoloid stock of eastern Asia (*see* Races of Mankind). They were preceded in the archipelago by the Negritos (*q.v.*), small Negroes related to those of the Andaman Islands and Malaya, who entered via land bridges at the height of the last glaciation, and survive today in the Bataan peninsula and other marginal areas. Discovery in 1958 of extinct fauna in apparent association with hand axes in the Cagayan valley make it probable that earlier types of man related to the Java series may have inhabited the area.

The Malay race is sometimes divided into an earlier Indonesian or proto-Malay element, with a more Caucasoid appearance, and a later, more Mongoloid Malay type characteristic of the coastal regions; but these distinctions are not clear-cut in the Philippines. The composition of the "Filipino blend," as it was called by archaeologist H. Otley Beyer, shows a number of earlier migrations, but the origins of the bulk of the population are to be sought in southeast Asia and Indonesia, where there are obvious resemblances in physical type.

2. Languages.—All of the Philippine populations, including the Negritos, speak languages belonging to the widespread Malayo-

PAUL ALMASY

FAMILY GROUP IN THE IFUGAO DISTRICT OF NORTHERN LUZON

Polynesian stock which includes most of the peoples of Oceania. Language offers an important clue to the history of Philippine groups, and according to Paul Benedict, the region of Hainan island is the probable "jumping-off" place for Malayo-Polynesian peoples for their journeys into Oceania.

About 75 linguistic groups are found in the Philippines, and today language is an important identifying feature of Filipino ethnic groups. Three or four of these groups are major languages which are gradually absorbing their smaller neighbours. Tagalog (*q.v.*), the most important of these linguistic groups, is second in size, but its strategic position in central Luzon led to its adoption in 1946 as the basis for the national language. Bisayan or Visayan, the largest major language group, occupies the central islands but is split into three subdivisions. In northern Luzon, Ilokano has become the dominant language.

Spanish was never widely used among the masses and declined sharply after World War II. English was the most widely used language at mid-20th century, being spoken by about 40% of the population, but Tagalog was also being taught in the schools and was increasing at a faster rate.

3. Religion.—The great bulk of the Philippine population is Roman Catholic, reflecting the long period of Spanish control. Islam was introduced prior to the Spanish conquest by Muslim traders from the south, but its spread was checked by the advent of the Spaniards until its resurgence in the 20th century. The aboriginal pagan religions are still to be found in the Mountain Province and Mindanao, though many of these groups have come under Christian or Muslim influence.

During the revolt against Spain the Philippine Independent church split off from Roman Catholicism under the leadership of Gregorio Aglipay. The Aglipayans, less than 10% of the population, have kept many aspects of Roman Catholic ritual but have modified doctrine, introduced the vernacular, and added national heroes to the roster of saints. The Aglipayans later divided into two groups, one of which affiliated with the Episcopal Church.

Protestantism entered the Philippines with the U.S. occupation. In 1925 there were about 22 independent national churches, and by the second half of the 20th century the number had more than doubled. With 2% to 3% of the population as members, most of these Protestant denominations are affiliated with the Philippine Federation of Christian Churches. An independent group, the Iglesia ni Kristo, grew rapidly in the post-World War II period.

4. Customs and Culture.—Filipino culture has roots far back in the past of the Malayan world, and has been profoundly influenced by Spanish culture and by U.S. training for independence. The major ethno-linguistic regional groups show a general cultural uniformity. Outside of the cities rice (or corn) agriculture and fishing furnish the basic subsistence; the family and the "kinship circle" are the centre of social life, and the annual cycle of ceremonies and fiestas of folk catholicism give colour and meaning to daily life.

In the Muslim areas in the south, there is a stronger development of political authority and territorial units, and the religious customs follow the Islamic pattern, but the other bases of life are similar to those in the Christian areas. Aboriginal cultures surviving in marginal regions show greater variability and retain some aspects of the pre-Spanish period. (F. R. E.)

III. HISTORY

The Philippine archipelago first became known to Europeans on March 16, 1521, through Ferdinand Magellan (*q.v.*). But there are authentic Chinese accounts of trading voyages as early as the 10th and 13th centuries, and the contact probably went back much further. A Hindu influence undoubtedly came by way of the Malay peninsula, Java and other islands nearby, and probably reached back to the early centuries of the Christian era. The Hindus influenced the life of the people intimately. Many Sanskrit words in the languages and dialects of the people of the Philippines and the forms of the letters used at the time of their discovery by the Spanish indicate this.

A. The Philippines Under Spain

The second, third and fourth Spanish expeditions were those of García Jofre de Loaisa, Alvaro de Saavedra and Ruy López de Villalobos. The next expedition, that of Miguel López de Legazpi (1564–72), was dispatched, like its predecessor, from New Spain, but it was far more carefully planned. Leaving Puerto de Navidad in New Spain on Nov. 20, 1564, Legazpi reached Cebu in April 1565, where the first permanent settlement was made early in May. But Legazpi, with inadequate forces and resources, meeting prolonged hostility from the Portuguese who also were present in the region, at last (1569) moved his main forces to the island of Panay, hoping thereby to have better protection. In 1571 Legazpi made Manila the administrative centre. Thereafter the conquest of Luzon proceeded rapidly, at first principally under Juan de Salcedo, the precocious young grandson of Legazpi. All the archipelago except the Moro islands of Mindanao, the Sulu archipelago and Palawan were in fairly peaceful possession of the Spaniards before 1600. In June 1572 the city of Manila was formally established. In 1574 Manila was attacked by the Chinese Limahong, but he was forced to retire from the island and from the entire group. Several of the provisional governors were churchmen who played into the hands of the ecclesiastics or catered to their own order.

1. Conquest.—The Spaniards were accepted easily, even hospitably in many cases, and the native populations coming into closest contact with them began almost immediately to take on a veneer of European culture. The conquest was especially easy along the coast and in the low interiors where the Spaniards first went. The principal opposition at Manila in 1570 came from Muslims, but that faith was not yet strongly entrenched in Luzon. The situation was quite different in Mindanao and at various other points in the south. The Spaniards were instinctive enemies of Islam, and it was they who gave the Philippine Muslims the name Moro (*q.v.*) by which they are still known. In 1574 the Moros of the Río Grande de Mindanao offered submission. In 1578–79 Francisco de Sande (governor, 1575–80) conducted a fairly successful expedition against the Moros, but the Spaniards were unable to gain any lasting advantage. Until 1837 piratical raids were almost continuous. The Moros ravaged the coasts far and wide, even threatening Manila itself. They often joined the Dutch after the latter began to be interested in oriental waters. In 1848 on Balanguingui Island, Gov. Narciso Clavería y Zaldua won the most decisive victory ever gained over the Moros. In 1850 Gov. Antonio de Urbiztondo y Eguía destroyed the strongholds on Tonkil Island and the next year stormed and captured the town of Jolo. This ended the real power of the Moros.

During the interim between Magellan's discovery and the settlement of Manila, the Portuguese actively contested Spanish right to the archipelago. Their hostility ceased only with the union of Spain and Portugal (1580–1640). In 1577 Sir Francis Drake started on the voyage which brought him to the Philippines at Mindanao. Again, in 1587, Thomas Cavendish sailed to the Moluccas and thence back to California to intercept the rich galleon "Santa Ana." He then went to the Philippines, where he tried in vain to capture the shipyard at Iloilo.

The Dutch came next. Their primary object was trade rather than colonies. In 1596–97 Adm. Cornelius Houtman opened trade with the Netherlands, and during the years 1598–1600 the expedition under J. C. van Neck and W. van Warwijck traded in the Moluccas. In 1600 Oliver van Noordt reached Philippine waters, where he committed various depredations. Dutch vessels now traded for spices and other oriental wares in the Moluccas, harried the coasts and waters of the Philippines and attacked Portuguese, Spanish, Japanese and Chinese shipping. In 1610 Gov. Juan de Silva defeated and killed the Dutch admiral Francis de Wittert at Playa Hondo, near Manila, and captured part of his fleet. In 1640 the Dutch captured Malacca and in 1662 they permanently occupied the Moluccas. Their attacks in the Philippines gradually ceased.

On Sept. 22, 1762, a British expedition reached Manila, found the Spanish but ill prepared and on Oct. 5 captured the city. By the treaty of Paris in 1763 Manila was restored to Spain.

With Legazpi had come five Augustinians; in 1577 came the Franciscans, in 1580 the Jesuits, in 1587 the Dominicans and in 1605 the Augustinian Recollects. It was the intention of Spain to replace the friars by secular parish priests whenever any mission assumed the character of a parish. But the friars, desirous of retaining their holdings and power, fought secularization and it was never carried out in its entirety. The friars became the storm centre of the gradually increasing Filipino demand for change; the insurrection of 1896 was directed principally against them, and during the later insurrection against the United States they suffered many indignities.

The last Manila galleon left the Philippines in 1811 and returned in 1815. Thereupon the trade was taken over by private persons, exports to the value of 750,000 pesos were allowed and three other ports besides Acapulco were opened to it, namely San Blas, Guayaquil and Callao. In 1766, however, the crown had allowed direct trade between Spain and Manila by one national vessel annually. In 1785 the Royal Company of the Philippines began to trade between Manila and Cádiz; the company ceased to exist in 1830.

In 1809 an English commercial house was permitted to establish itself in Manila, and in 1814 a like privilege was extended to all foreigners. As a rule, however, Spaniards were still jealous of foreigners, and reactionary decrees in 1828 and 1840 forbade them to sell goods at retail or to do any business in the provinces. The vacillating Spanish policy is seen again in the opening of seven ports to foreign trade in 1830 and their closing the next year. In 1837 Manila was reopened to foreign trade, and Iloilo and Cebu were reopened in 1855 and 1863. In 1842 there were 39 Spanish shipping and commercial concerns in Manila and about a dozen foreign houses. Various governments maintained consuls, among them Great Britain and the United States.

2. Philippine Nationalism.—During the first half of the 19th century, there were only from 2,000 to 5,000 Spaniards in the archipelago. Spanish was spoken by some of the natives, principally in Manila and a few other important centres, but the friars had made comparatively little effort to inculcate a knowledge of Castilian. There was no homogeneity among the several native peoples, very largely because of the different languages. Partly because of these conditions, insular representation in the Spanish *Cortes* carried little meaning or a mistaken one to the mass of the population. After the building of the Suez canal, in 1869, ambitious Filipino youths went to Spain and other countries for study. The first daily newspaper was *La Esperanza* (1847). *La Solidaridad* was founded in 1888 in Barcelona by Graciano López Jaena in the interest of Filipino propaganda, and throughout its course it urged reforms in both religion and government. One of its foremost contributors was the precocious Chinese mestizo, José Rizal y Mercado. The Filipinos had ample grounds for complaint, especially after 1872. That year about 200 native soldiers at the Cavite arsenal revolted, killed their officers and shouted for independence. Plans for a similar demonstration in Manila failed. The insurrection was quickly suppressed, and led to wholesale arrests, life imprisonment and the execution, among others, of three Filipino secular priests, whose connection with the uprising was not satisfactorily explained.

Meanwhile the gradually expanding idea of Filipino nationality began to manifest itself. The campaign of Rizal, Marcelo del Pilar, López Jaena and Apolinario Mabini, leaders in the Young Filipino party, was a protest against both the domination of the friars and economic and administrative caciquism. These aspirations met a sympathetic reception from several governors, but other Spaniards, especially the friars, were diametrically opposed; and much of the old easy and cordial intercourse between the two peoples was changed. Rizal threw himself into the propaganda with eagerness. In 1891 he founded at Hong Kong an organization called the Liga Filipina, and in 1892 formed a branch at Manila. He was arrested in 1896 at Barcelona, returned to the Philippines, given a farcical trial and executed on Dec. 30, 1896. At about the time of Rizal's establishment of the Liga Filipina there was also founded an organization called the Supreme Worshipful Association of the Sons of the People, which is generally called the Katipunan. The organization was altogether Tagalog and is said to have numbered anywhere from 100,000 to 400,000 members. On Aug. 26, 1896, the actual insurrection broke out. "The cry of Balintawak" is the name given to the first hostilities by the Filipinos. The centre of the revolt was in Cavite province, where Emilio Aguinaldo first came into prominence. Spain sent over reinforcements until there was an army of 28,000 besides a few loyal regiments of native soldiers. A stiff campaign of 52 days brought the defeat of the insurgents, but upon the execution of Rizal the insurrection broke out again and spread to the provinces of Pangasinan, Zambales and Ilocos. Fernando Primo de Rivera opened negotiations with Aguinaldo and concluded with the insurgents the pact of Biac-na-Bató. Accordingly, Aguinaldo left for Hong Kong on Dec. 27, 1897. With the blowing up of the "Maine" on Feb. 15, 1898, actual hostilities broke out between Spain and the United States. (*See* SPANISH-AMERICAN WAR.)

Aguinaldo returned to the Philippines May 19, 1898, and announced renewal of the struggle with Spain. The Filipinos, who declared their independence of Spain on June 12, 1898, proclaimed a provisional republic with Aguinaldo as president, and on Sept. 9, 1898, moved their capital to Malolos, with Apolinario Mabini, the "mouthpiece of the revolution," as Aguinaldo's chief adviser. A revolutionary assembly met on Sept. 15 and on Sept. 29 ratified Filipino independence. In November and December revolutionary tribunals were organized in the Visayas. The Philippines, along with Puerto Rico and Guam, were ceded by Spain to the U.S. by the Treaty of Paris, Dec. 10, 1898.

B. The Philippines Under the United States

1. The Insurrection.—Relations between the Americans and the Filipinos were unfriendly and grew steadily worse. On Jan. 23, 1899, the Malolos constitution, by virtue of which the Philippines were declared a republic and which had been approved by the assembly on Nov. 29 and by Aguinaldo on Dec. 23, was proclaimed. Aguinaldo, who had been president of the provisional government, was elected president.

On the night of Feb. 4 the inevitable conflict between the Americans and Filipinos surrounding Manila was precipitated. Morning found the Filipinos, who had fought bravely, even recklessly, defeated at all points. While the fighting was in progress, Aguinaldo issued a proclamation of war against the United States. On Feb. 6 the U.S. senate ratified the treaty with Spain, and reinforcements were immediately sent to the Philippines. Antonio Luna, the best-trained military man among the Filipinos, was given charge of military operations, but seems to have been greatly hampered by the jealousy and distrust of Aguinaldo, which he

fully returned. Luna was murdered, and on March 31, 1899, Malolos was captured by the U.S. forces. The Filipino government fled northward. In Nov. 1899 the Filipinos resorted to guerrilla warfare, with all its devastating features. The capture of Aguinaldo by Gen. Frederick Funston in March 1901 virtually ended the real insurrection, although the last surrender was that of Gen. Miguel Malvar in Samar on April 16, 1902. The major operations of the insurrection were conducted in Luzon, and throughout the army was assisted materially by the Makabebe scouts, who remained loyal to the U.S. Meanwhile, on April 7, 1900, Pres. William McKinley instructed the second (Taft) commission to "bear in mind that the government which they are establishing is designed not for our satisfaction nor for the expression of our theoretical views, but for the happiness, peace and prosperity of the people of the Philippine Islands." Nothing was said about independence, although the instructions were later often cited in support thereof.

2. Taft.—Gov. William Howard Taft initiated negotiations with Pope Leo XIII for the purchase of friar lands (about 400,000 ac.) which were finally bought Dec. 23, 1903, at a price of approximately $7,250,000. Taft pledged the credit of the Philippine government for the amount, and bonds were issued therefor. A considerable portion of the lands, of high agricultural quality, were later sold to Filipinos. The pope also replaced the Spanish archbishop and bishops with U.S. prelates.

In 1904 Taft was called home to become secretary of war, but he continued to govern the Philippines from Washington, D.C. In 1905 he took a party of senators and representatives to the islands, at the expense of the Philippine government, and on Oct. 16, 1907, on the eve of his presidential campaign, he opened the first Philippine legislature at Manila, although there was still fighting in the Visayas and the act of 1902 required a state of "complete peace" before convening the legislature. Among other acts, that body voted to continue both Spanish and English as official languages until 1913, when Spanish was to be dropped. That, however, was never accomplished, and it was not until 1940 that Tagalog was added as another official language. On Aug. 6, 1909, congress passed the Payne bill, granting important trade concessions to the Philippines, and in 1913 the Underwood act provided for complete free trade between the islands and the United States. This concession continued until Jan. 1, 1941.

3. The Governors General.—Taft was succeeded as governor by Luke E. Wright of Tennessee, who had been a member of the Philippine commission and became the first American to bear the title of governor general. Serving from 1904 to 1906, he was very popular with Americans; but his firm and conservative policy failed to suit the more radical Filipinos and he was transferred to Tokyo as minister. Henry C. Ide of Vermont was the next incumbent of the office. He too was a member of the Philippine commission and had seen service in Samoa during the partition of that group. He was a wise and able administrator but was permitted to remain as governor general for a few months only. He was succeeded by James F. Smith of California, who had come to the islands as a colonel of volunteers and later served on the supreme court and the Philippine commission. It was understood that he was much opposed to accepting the governorship but that Taft insisted on having a Catholic for the office. Smith served from 1906 until 1909. On Nov. 11 of that year, W. C. Forbes of Massachusetts was inaugurated as governor general, serving until Aug. 1913, when he was removed. Some of his acts occasioned bitter controversy (such as his deportation, without trial, of a large and prosperous group of Chinese merchants who had been long established in Manila), and his administration was a stormy one. Francis B. Harrison of New York succeeded and served from 1913 to 1921, the longest term of any U.S. governor general.

The Wood-Forbes mission, sent by Pres. Warren G. Harding in the first year of his administration, reported that the grant of immediate independence would be premature and urged that the U.S. government not be left in a position of responsibility without authority. Leonard Wood, a major general in the regular army and the former military governor of Cuba and later of the Philippine Moro province, seemed unusually well equipped for the governor generalship to which President Harding appointed him, effective Oct. 6, 1921. But by that time the Filipino leaders, having had a taste of power under Wood's predecessor, were in no mood to submit to authority if actually exercised. He administered the government through undersecretaries until 1927, when he died in Boston, Mass. Meanwhile, Pres. Calvin Coolidge had sent Carmi Thompson of Ohio "to investigate and report" on the Philippines. He made the trip with considerable publicity and likewise reported against the grant of independence, but recommended certain reforms.

Henry L. Stimson of New York was the next governor general. As secretary of war in the Taft administration he had acquired considerable familiarity with Philippine affairs, and he had just returned from a successful mission to untangle a difficult situation in a middle American state. Proceeding with tact and caution, he gradually won over the Filipino leaders, obtained some reforms and was about to secure others, when he was called home in 1929 by Pres.-Elect Herbert Hoover to become secretary of state.

In May 1930, Dwight F. Davis of Missouri, who had also been secretary of war, was appointed. His administration was uneventful, as was that of Theodore Roosevelt, Jr., who succeeded him in 1932. Pres. Franklin D. Roosevelt appointed Frank Murphy of Michigan, a strong advocate of independence, who took office as governor general June 15, 1933, and served until Nov. 15, 1935, when he became the first high commissioner in the Philippines. Leaving that post in 1936, Murphy was succeeded by Paul V. McNutt of Indiana, who served until 1939. He realized the value of the islands as a source of supply for tropical products and for their mineral wealth, and evidently felt that the grant of independence was a mistake for both countries. But it was now too late to effect any change in the general policy. Francis B. Sayre of Massachusetts, who was appointed to succeed him, arrived in Manila Oct. 21, 1939. He had been on the faculty of Harvard university and later an assistant secretary of state. His prescribed task was to prepare for independence.

4. Campaign for Independence.—As early as 1929, the campaign of the Filipinos for that goal had been gaining momentum, with new allies, in the United States, among producers of sugar, tobacco, fats and other products and the labour unions which feared the competition of Filipino immigrants. A bill supported by these interests and providing for independence finally passed both houses of congress, was vetoed by President Hoover, passed again over the veto in Jan. 1933, but failed of ratification by the Philippine legislature because of opposition by Manuel Quezon, who, his opponents declared, wished to divert credit from those who had secured passage of the bill in his absence from Washington. This would have been an opportune time to re-examine the whole question, for the Filipinos had been given their long-sought chance and had rejected it. But the U.S. interests were determined to push the measure through. Quezon hurried to the United States to win President Roosevelt's support for a new bill, differing but little from its predecessor, but omitting the important provision reserving absolutely, as in Cuba, sites for naval bases, etc.

The new bill, known as the Tydings-McDuffie act—public law 127—passed both houses of congress, received presidential approval March 24, 1934, and was ratified by the Philippine legislature on May 1. It established a Philippine commonwealth, provided for independence in 1946 and for a graduated tax on Philippine exports to the United States (to be collected by said government for a sinking fund for bonded indebtedness) of 5% of the corresponding U.S. duty for the first year, beginning Jan. 1, 1941, and increasing by 5% each subsequent year. This was amended by the act of 1939 (public law 200), exempting cigars, scrap and filler tobacco, coconut oil and pearl or shell buttons, which were all subjected to free quotas, reducible by 5% each year. Hemp and copra were already on the free list. The U.S. immigration laws were applied, and the annual Filipino quota was limited to 50.

Pursuant to the act, a constitutional convention assembled in Manila July 30, 1934, and remained in session until Feb. 8, 1935, when a draft constitution was approved. It was certified by President Roosevelt on March 23 and ratified on May 14 of the same year by popular vote. It was on the whole a creditable document;

but two of its unique features—a single six-year term for the presidency and a unicameral legislature—were eliminated by amendments adopted in 1939 and approved by President Roosevelt Dec. 2, 1940. Quezon, elected first president of the commonwealth in Sept. 1935, was re-elected for a four-year term Nov. 4, 1941, but with the understanding—not legally enforceable—that he would give way to Vice-Pres. Sergio Osmeña after two years. The Philippine army, trained under Douglas MacArthur, son of the last American military governor, was called into the U.S. service on July 26, 1941, in time to help meet the Japanese invasion, Dec. 8 (Philippine time). (*See* WORLD WAR II.)

With the Japanese invasion, Quezon, Osmeña and the commonwealth cabinet left the Philippines to conduct a government in exile in Washington. Osmeña became president upon the death of Quezon in Aug. 1944 and returned to the Philippines when U.S. forces made their first Philippine landings on Leyte Island Oct. 20, 1944. General MacArthur proclaimed the liberation of the Philippines in July 1945. In general elections held in April 1946, Osmeña was defeated by Manuel Roxas y Acuna, who served as the last president of the commonwealth and within a few months became first president of the Republic of the Philippines.

C. The Philippines After Independence

On July 4, 1946, the commonwealth ended and the Republic of the Philippines came into existence as a sovereign independent state. In contrast with the transition which had been envisaged at the time of the Tydings-McDuffie act of 1934, the Philippines had suffered invasion, a three-year Japanese occupation and the added war damage of liberation. An estimated 1,000,000 lives had been lost as a result of the war. The damage to major industries was estimated as follows: shipping 85%, transportation 70%, mining 80%, sugar production 65% and coconut oil production 95%. Losses in production of rice, hemp, lumber and tobacco and in the fishing industry were estimated at $117,000,000. Damage to dwellings, port facilities and communications was extensive. Manila was one of the world's most devastated capitals. In addition to a shattered economy, the Roxas government was confronted with political controversy and an incipient Communist-led rebellion.

Immediately prior to independence the United States had acted to assist the Philippine government in restoring the economy. On April 30, 1946, Pres. Harry S. Truman signed the Philippine Rehabilitation (war damage) act and the Philippine Trade act of 1946. The Rehabilitation act authorized the appropriation of $620,000,000 to meet war damage claims and for Philippine government reconstruction programs and authorized 12 United States government agencies to engage in rehabilitation programs in the Philippines. The Trade act extended the period of duty-free trade until 1954 with an increase of 5% of the full tariff rate to be applied thereafter. The act provided that no change would be made in U.S. import quotas of Philippine sugar and cordage for a period of 28 years. A military assistance pact authorizing the establishment of U.S. bases was signed March 14, 1947. This was followed by a mutual defense treaty signed Aug. 30, 1951.

Pres. Elpidio Quirino became chief executive upon the death of Roxas on April 15, 1948. Within one year the deficit in the general fund was reduced from 153,000,000 pesos to less than 1,000,000 pesos.

During the Quirino administration the Hukbalahap movement became a threat to the republic. This movement had developed during the Japanese occupation as a guerrilla army to fight Japan. After the defeat of Japan the Huks, as they were called, turned against landowners and, in the interest of gaining reforms, committed acts of violence and terror principally in central Luzon and in Panay. At the end of 1949 the Huks renounced reform by constitutional means, became identified with the Communist party and advocated the forceful overthrow of the government. In 1951 Secretary of Defense Ramón Magsaysay began a program of combined military pressure and granting of homesteads on the island of Mindanao to surrendered Huks. By Dec. 1955 the Huk rebellion had died out.

Magsaysay was elected president of the republic as candidate of the Nationalist party in the elections of Nov. 1953. He was elected on a platform promising real reform in government. During Magsaysay's first year in office, he succeeded in dominating the professional politicians of his Nationalist party. Early in May 1954 the president relinquished the post of minister of defense, feeling that the problems of internal security were under control. The chief Hukbalahap leader, Louis Taruc, surrendered to the government during that month. Major progress in opening new land settlements outside crowded Luzon had taken the edge off agrarian unrest, though the basic issues of land reform had not yet been carried out in Luzon itself. President Magsaysay had at least temporarily stopped trends of opportunism among his political opponents by committing the Philippines to participation in the free world's collective security programs against Communism, and to the maintenance of the strong traditional ties to the U.S.

The main problem facing the Magsaysay administration in the mid-1950s was unemployment, a result in part of stagnation in the Philippine economy. Magsaysay, who died in a plane crash in March 1957, was succeeded by Vice-Pres. Carlos P. García. García, a member of the Nationalist party, was then elected president on Nov. 12, 1957.

In preparation for the 1961 presidential elections the Progressive and Liberal parties merged to form a united front against the Nationalists. They nominated Diosdado Macapagal, vice-president under García, as their presidential candidate, while the Nationalists chose García to run for re-election. On Nov. 14, 1961, Macapagal defeated García for the presidency; the Liberals also won the vice-presidency but the Nationalists retained control of both houses of congress.

Following independence the United States and the Philippines joined in treaty arrangements for the defense of the islands. Under the terms of a military bases agreement concluded in March 1947, the use of designated military, naval and air bases was granted to the United States for a period of 99 years. In Aug. 1951 a mutual defense treaty was signed between the two countries. In Sept. 1954, at a conference in Manila, the Philippines joined with seven other nations (Pakistan, Thailand, Australia, New Zealand, France, the United Kingdom and the United States) in forming the Southeast Asia Treaty Organization (SEATO), which committed the members to act against aggression, colonialism and internal subversion in the treaty area.

On May 15, 1958, a new U.S.-Philippine defense agreement was announced which established a mutual defense board and resolved the question of U.S. military bases. A memorandum signed Oct. 12, 1959, shortened the 99-year lease originally signed in 1947, to 25 years.

IV. POPULATION

The population of the Philippines in 1960 was 27,087,685, an increase of almost 8,000,000 since 1948 (19,234,182), or an average annual increase rate of more than 3%. The 1964 estimate indicated a total population of 31,764,000.

Of the total population in 1960, only 14.3% lived in towns and cities with populations of over 5,000, and almost one-third of these were concentrated in the city of Manila. Manila alone had a population of 1,138,611 in 1960. Other cities, Quezon City (397,990), Cebu City (251,146), Davao (225,712), Basilan (155,712), and Iloilo (151,266), also had considerable population concentrations. Although the populations of these and other urban centres increased greatly between 1948 and 1960, the larger percentage of the Philippine population continued to live in rural villages of fewer than 1,000 persons. Thus the Philippines can be characterized as a predominantly rural country. The average density of population in 1960 was 235.9 per square mile. The areas of greatest density were the city of Manila (81,329) and the provinces of Rizal (1,841), Laguna (1,015) and Cavite (759), while Palawan (29) and Mindoro Occidental (41) were the most sparsely populated.

V. ADMINISTRATION AND SOCIAL CONDITIONS

1. Government and Administration.—During the period of United States control, from 1898 until the Philippine republic attained sovereignty on July 4, 1946, the Philippine citizens in-

Area and Population by Province

Province (with capital city)	Area (in sq.mi.)	Pop. (1960 census)	Density per sq.mi.

creasingly were granted and assumed the responsibilities of self-government. With the end of military government on July 4, 1901, a civil government was established under a governor (later called governor general). On July 1, 1902, the U.S. congress passed an enabling act providing for a popularly elected assembly which would constitute the lower house of a Philippine legislature. The Philippine commission, which consisted of seven members appointed by the president of the United States, would serve as the upper house. An election of members of the assembly was held on July 30, 1907. Under the provisions of the enabling act two resident commissioners were appointed to the United States with power to speak on legislation affecting the Philippines but with no vote. In 1909 the Philippine commission was expanded to include four Filipinos.

The Jones act of Aug. 29, 1916, provided for the replacement of the Philippine commission by an elected senate of 24 members and for a house of representatives of 91 (later 92) members. The act proclaimed a bill of rights.

The Philippine Commonwealth and Independence act (Tydings-McDuffie act) abolished the office of governor general and placed remaining United States authority in a high commissioner. The commonwealth government was established in Nov. 1935 with Manuel Quezon as its first president. While the islands were under Japanese occupation during World War II, the commonwealth government continued to operate in exile in the United States.

When the Republic of the Philippines became a sovereign and independent state, no substantial changes were made in the structure of government provided in the constitution of 1935 (as amended in 1940 and 1946). By the amendment of 1940, executive power was lodged in a president and vice-president, elected for terms of four years with eligibility for re-election.

The legislative power was vested in the congress of the Philippines, composed of the senate and the house of representatives. It was provided that the 24 members of the senate be elected at large by direct popular vote for six-year terms and the members of the house of representatives, representing 102 congressional districts, be elected for terms of four years.

Judicial power was vested in the justices of the supreme court (the highest tribunal), the court of appeals, courts of first instance, municipal courts of chartered cities and justices of the peace. All justices and judges were appointed by the president.

Each of the 53 provinces of the Philippines in 1958 (later increased to 55 provinces) was governed by a provincial board composed of the governor and two other board members, all elected. The 1,078 municipalities were administered by elected mayors and had municipal councils.

The governing body of each of the 30 chartered cities in 1958 was a municipal board composed of a mayor, vice-mayor and councilors. The members might be either appointed by the president or elected as provided by the charter. Quezon City, east of Manila, was designated as the national capital and by the late 1950s construction of several government buildings was under way, but most of the functions of national government remained in Manila. The 55 provinces, their areas and capital cities are shown in the population table.

2. Education.—The educational system of the Philippines is the most extensively developed in the orient. During most of the Spanish period, elementary education was undertaken only by the pastors and curates of parishes and was designed primarily to inculcate Christian values. A decree in 1863 established a compulsory educational system under civil control. Although this decree was never fully implemented, educational facilities and opportunities were expanded. A program of mass education was begun in 1901 under United States civil government; soldiers had acted as teachers for about two years prior to that time. The program sought to develop free political institutions through universal education. In 1901, 1,000 U.S. teachers were brought en masse to the Philippines. English was established as the medium of instruction and remained so. A system of scholarships was set up to train Filipinos in U.S. colleges and universities. The educational system thereafter continued to expand rapidly. The Philippine people eagerly adopted the U.S. concept of education. Education is highly valued as a factor in individual advancement and national development. The republic is perhaps unique in that the majority of the rural elementary schools have been built directly by the people through private initiative and planning. The educational system is highly centralized, with administrative control in Manila. Public education embraces all levels: elementary school, four years; intermediate school, three years; secondary school, four years; college and university. There are public schools for arts and trades, commerce, agriculture and fishing. Tuition is paid from the secondary level on, but many scholarships are available. The private educational system is vitally important, particularly at secondary, normal, collegiate and university levels. All private schools are supervised and accredited by the government.

Education is the second largest item in the national budget, amounting each year to nearly 20% of the total. The literacy rate of those persons 10 years old and over in the early 1960s stood at about 72%, the highest in southeast Asia.

3. Defense.—There is a program of mutual defense and cooperation with the U.S. and SEATO (*see* History above). The Philippine constabulary and local police maintain public order. The former is part of the armed forces whose chief of staff has over-all command of the land, sea and air forces.

VI. THE ECONOMY

A. Finance and Trade

1. National Finance.—The Philippines entered the period after World War II under financial difficulties. Large reconstruction costs were only partly compensated by U.S. financial aid and war damage compensation, and government deficits, as well as trade deficits, were normal, owing in good part to large-scale development programs.

The Philippine Central bank's foreign exchange reserves fell from 800,000,000 pesos at the end of 1948 to 450,000,000 pesos on Dec. 9, 1949. On that date controls were imposed, placing all foreign exchange under licencing. The economic and fiscal position of the Philippines continued to decline, and the Bell mission recommended in 1950 that, among other measures, taxes be increased and reforms be made in tax collection procedure. During 1951 tax machinery was improved and new taxes were imposed, including a tax of 17% on the sale of foreign exchange.

During 1949 and 1950 import controls had been established as a measure to stimulate Philippine production and to conserve foreign exchange. This resulted in a decline in the yield of some internal taxes but it improved the general financial position. A partial relaxation of import controls in 1951 contributed to a government surplus in 1952. The degree of import control varied after 1952. Throughout the 1950s national government expenditures slightly exceeded revenue for each fiscal year.

The international reserve had reached a high point of 782,500,000 pesos on April 30, 1951, after the low level in 1949, but it declined slowly after that.

In addition to the Central bank, there are more than 15 commercial banks with more than 100 branches and agencies, a few savings and mortgage banks, and numerous rural banks. Banking operations are also conducted by the Postal Savings bank, the Agricultural Credit and Cooperative Financing administration, the Rehabilitation Finance corporation, building and loan associations and pawnshops.

2. Trade.—During the period the Philippines were under Spanish rule, external commerce for the most part was limited to trade with Spain and Mexico. Under United States sovereignty, foreign trade expanded. With the passage of the Paine Tariff act of 1909 and later the Underwood act of 1913, providing for unrestricted free trade between the two countries, the Philippines became largely dependent on the U.S. market. In pre-World War II years more than 65% of Philippine trade was with the United States. During the years after independence trade with the United States declined from 86% of the total trade of the Philippines in 1945 to about 50% in the mid-1960s.

Although the Philippine prewar exports were sufficient to offset imports, the wartime scarcity of consumer and hard goods resulted in an unfavourable balance of trade in the postwar period. The leading postwar exports were copra, sugar, abacá, abacá manufactures, coconut oil, base metals, lumber, canned pineapple, dried coconut and embroideries. Among the principal imports were textiles, grains and preparations, petroleum, automobiles, iron and steel, tobacco, dairy products, paper and machinery.

WOMAN COLLECTING RICE SEEDS IN A COURTYARD OVERLOOKING ANCIENT RICE TERRACES OF NORTHERN LUZON

B. Production

1. Agriculture.—The fertile soil and tropical climate of the Philippines are well adapted to the raising of agricultural products, and farming engages about two-thirds of the employed population.

The total land area of the Philippines is 29,741,000 ha. (1 ha. = 2.471 ac.). The 1962 area planted totaled about 8,000,000 ha., with 70% in domestic food crops, and 30% in export crops. Rice is the principal staple food of the Filipinos, and in 1962 it was harvested from about 3,000,000 ha. (40%) of the cropland. The 1962 yield of about 4,000,000 metric tons was the highest on record and fulfilled the domestic requirement. Corn, another important food crop, also increased steadily to 26% of the cropland, about 2,000,000 ha., in 1962. Fruits, nuts and root crops occupy significant shares of the cropland, and vegetables, beans and peas, coffee, cacao and peanuts are domestically important.

Among the export crops, coconut was the leader in 1962, occupying over 1,000,000 ha., or 16% of the total cropland; this was slightly lower than the 1940 figure. Coconut products such as copra, coconut oil, desiccated coconut and copra cake form the leading export of the islands. Sugar cane revived to exceed its prewar acreage and production, but is no longer the chief money crop. Abacá declined slightly in relative importance in the economy. Tobacco is a minor crop and export, as are ramie, kapok, rubber, pineapple and derris.

Next to farming, livestock raising engages the greatest number of persons. The carabao (water buffalo) is the beast of burden upon which the Philippine farmer depends. As a result of the destruction of livestock during World War II the total number remaining in 1949 was estimated at less than 2,000,000. By 1962 the livestock population was as follows: carabao, 3,500,000; cattle, 1,000,000; horses, 210,000; hogs, 6,725,000; goats, 628,000; sheep, 23,000; and poultry, 53,000,000.

2. Forestry.—The Republic of the Philippines is one of the world's largest lumber-producing countries, ranking fifth in the ratio of forests to total land area. Commercial forests, which cover 34% of the total area of the Philippines, were placed under the administration of the bureau of forestry under a licencing system. In addition to building lumber and hardwoods, forest products include dyewoods, rattan, tanbarks, bamboo, gutta-percha, gum copal and fibres.

3. Fisheries.—Fishing is an important industry, ranking next to farming and livestock raising in the number of persons depending upon it for their livelihood. Fish comes next to rice in importance in the Filipino diet. About 1,900 different species of fish are found in Philippine waters, of which the commonest are milkfish, mackerel, snappers, sea bass, porgies, pompanos, mullets, anchovies, barracuda, tuna and bonito. Before World War II the average annual commercial inshore catch amounted to about 21,000 tons in addition to 25,000 tons produced in fish ponds. Total fish production in 1961 was 455,000 metric tons. Canned tuna is the principal fish exported. Other marine products include coral, pearls, shells and sponges. Among the shells and shell products are mother-of-pearl, trochus, tortoise, green snail shells and shells used for windows.

4. Mining.—The mineral wealth of the Philippines includes deposits of gold, silver, iron, copper, chrome, manganese and lead.

BY COURTESY OF PHILIPPINE ASSOCIATION; PHOTOGRAPH, CHARLES MILLER

PART OF DOWNTOWN MANILA AND THE PASIG RIVER. THE BUILDING IN THE CENTRE IS THE POST OFFICE

In addition to the base metals, such nonmetallic minerals as asbestos, asphalt, marble, coal, gypsum, limestone, clay, petroleum and building stone are found.

Gold deposits are in Baguio on Masbate; and in Surigao, Davao and Zamboanga on Mindanao. Iron deposits are found in Camarines Norte and Bulacan on Luzon and in Surigao. Chromite and copper are mined in Zambales on Luzon. Manganese is found in Ilocos Norte and Zambales on Luzon; on Palawan and Siquijor.

Gold and iron mining are old industries, with records of gold mining by crude methods prior to the arrival of Magellan. Coal mining dates from the early Spanish period. Petroleum formations are known to exist, and prior to World War II there were a few producing wells; in 1939, however, all petroleum lands were withdrawn from entry for five years pending the development of exploitation plans. During the Japanese occupation the mining industry suffered from lack of maintenance and the looting of equipment. After independence, the mining industry was the last of the major prewar industries to be rehabilitated.

While gold production had been 1,033,037 oz. in 1939, representing a 64% increase over production in 1929, in 1961 production was only about 424,000 oz. Silver production in 1961 was 813,000 oz. as compared with the production of 1,175,000 oz. in 1938. The production of other minerals in 1961 (in metric tons) was: zinc, 3,000; lead, 100; copper, 57,000; iron ore, 1,170,000; coal, 152,000; chromite ore (refractory) 485,000 and (metallurgical) 145,000; and manganese ore, 19,000. Total value of mineral production in 1961 was more than 300,000,000 pesos.

5. Industry.—Industrial development, speeded during the period of the commonwealth, was devoted primarily to the manufacture and processing of agricultural products. Among these were: sugar, rope, cigar and cigarette, cordage, wood and rattan furniture factories; sugar, rice and lumber mills; pineapple and fish canneries; beer distilleries; and spinning mills. During the years immediately preceding the war, modern factories were established for producing shoes, hats, leather products, perfume and pearl buttons. Household industry produced embroideries, candies and fibre hats.

After independence in 1946, new industries were developed as a result of government-imposed import controls, government loans and legislation exempting new industries from taxation for a period of four years. These included an oil refinery and factories producing chemical products, fibre products, aluminum and enamelware, medical supplies, radios and musical instruments, wood and pulp products, knitted goods of rayon and cotton, plastics, rubber and steel products.

The National Development company, established during the commonwealth period and reorganized following independence, engaged in enterprises deemed in the interest of a systematic development of Philippine resources. Its subsidiary corporations included the National Food Products corporation, National Rice and Corn corporation, Peoples Homesite corporation, National Footwear corporation, Insular Sugar Refining corporation, National Tobacco corporation, Manila Railroad company and others.

The National Development company participated directly in the construction of hydroelectric plants, a steel mill, shipyards, steel-products plants, pulp mills, heavy-machinery shops and spinning mills. The Rehabilitation Finance corporation granted loans to private investors for approved industrial enterprises.

C. Transport and Communications

During World War II transportation and communication facilities were badly damaged, but after the war they were substantially rehabilitated. In the mid-1960s there were about 30,000 mi. of roads in the Philippines. The railways are of the narrow-gauge type. The Manila Railroad company, owned by the Philippine government, operates a system of more than 600 mi. in Luzon extending from San Fernando, La Union, in the north to Legaspi, Albay, in the south. The Philippine Railway company has about 100 mi. of railways in the islands of Panay and Cebu.

Because of the republic's insular nature interisland shipping between the more than 200 local ports is an important factor in domestic trade and communications, and more than 3,000 vessels are engaged in this local trade. Foreign shipping, which more than doubled after World War II, is handled through the ports of entry, Manila being the largest and most important of these. Other ports of entry include Cebu, Iloilo, Zamboanga, Davao, Tabaco, Tacloban, Jolo, Jose Pañganiban, San Fernando and Aparri.

Philippine Air Lines services more than 30 stations within the islands and maintains international connections with Hong Kong. Several international airlines also stop at the Philippines.

Of the more than 130,000 telephones in use in the republic in the mid-1960s, more than half were in Manila. (R. E. He.)

PHILIPPINE SEA, the name applied since 1944 to that part of the western North Pacific Ocean lying east and north of the Philippines. The floor of the Pacific in this area is formed into a natural basin by a series of geologic folds and faults in the form of arcs. These arcs protrude above the surface in many places, forming a series of bordering islands. The Philippine Islands of Luzon, Samar, and Mindanao are on the southwest; Palau, Yap, and Ulithi of the Caroline Islands are on the southeast; the Marianas, including Guam, Tinian, Saipan, and others, are on the east; the Bonin and Volcano Islands, including Iwo Jima, Kita Iwo, and others, lie to the northeast; the Japanese islands of Honshu, Shikoku, and Kyushu lie to the north; the Ryukyu Islands, including Okinawa, are to the northwest; Formosa marks the extreme western edge of the sea. Maximum measurements for the Philippine Sea are 1,800 mi. (2,900 km.) from north to south and 1,500 mi. (2,400 km.) east to west. Ocean trenches, or deeps, mark the eastern sides of the various folded arcs. Within the Philippine Sea are located the Ryukyu trench and the Philippine or Mindanao trench (Mindanao deep). The latter reaches the second lowest depths known in any section of the ocean floors. Maximum depth is achieved about 120 mi. (190 km.) northeast of the town of Surigao on northeastern Mindanao. The depth here is 34,583 ft. (10,541 m.), recorded in 1951 by the Danish oceanographic ship "Galathea," correcting a 1945 reading of 34,440 ft. (10,497 m.) recorded by the USS "Cape Johnson" and a 1927 reading of 35,400 ft. (10,790 m.) recorded by the German cruiser "Emden." The warm North Equatorial current flows westward across the southern part of the sea. Upon meeting the Philippine Islands the current divides; part swings north as the warm Kuroshio or Japan current and part swings toward the Equator as the Counter Equatorial current.

PHILIPPINE SEA AND SURROUNDING ISLANDS

During World War II the U.S. Navy achieved two significant victories over the Japanese fleet in the southern Philippine Sea. The first was fought by carrier planes alone on June 19–20, 1944. The second, sometimes called the Battle of Leyte Gulf, involved the major units of both fleets and was a decisive American victory. *See* World War II: *The War at Sea*. (R. E. He.)

PHILIPPOPOLIS: *see* Plovdiv (Bulg.).

PHILIPS, AMBROSE (1674–1749), English poet whose contemporary reputation rested chiefly on his *Pastorals*, was born at Shrewsbury, Oct. 9, 1674. He was educated at Shrewsbury school and St. John's college, Cambridge, where he became a fellow in 1699. In 1700 he published *The Life of John Williams*, an abridgment of J. Hacket's *Scrinia Reserta, A Memorial to Archbishop Williams* (1693). After traveling in Holland, he obtained a commission and served in Spain. In 1709 his *Pastorals* appeared in J. Tonson's *Miscellany* and won praise from Addison, Steele and Pope. They were later parodied by John Gay in *The Shepherd's Week* (1714). Philips became secretary to Daniel Pulteney, the British envoy at Copenhagen, in 1709 and there composed a widely admired verse epistle to the earl of Dorset, *A Winter Piece* (1709). After tutoring in Italy he returned to London, where *The Distrest Mother* (1712), his adaptation of Racine's *Andromaque*, was a success. His other plays are *The Briton* (1722) and *Humfrey, duke of Gloucester* (1723). His quarrel with Pope, described by Dr. Johnson as a "perpetual reciprocation of malevolence," resulted from an article in *The Guardian* (No. 32 of 1713) in which Philips, and not Pope, whose *Pastorals* had also appeared in Tonson's *Miscellany*, was hailed as the successor of Theocritus, Virgil and Spenser.

Gradually Philips lost his literary friends. In 1714 he was made paymaster to the lottery, and justice of the peace for Westminster; but in 1724 he became secretary to Dr. Boulter, archbishop of Armagh, whom Swift detested, and found himself the butt of literary Dublin. His poems on the children of Lord Carteret and Daniel Pulteney, scoffed at by Swift as "little flams," were parodied, and he was nicknamed "Namby Pamby." He sat in the Irish parliament and held legal positions before returning to London in 1748. He died there, June 1 or 2, 1749. His *Poems* were edited with an introduction by M. E. Segar in 1937.

PHILIPS, JOHN (1676–1709), English poet and man of letters, best known for his brilliant parody of the Miltonic style in *The Splendid Shilling*, was born at Bampton, Oxfordshire, on Dec. 30, 1676, the son of Stephen Philips, archdeacon of Shropshire. He was educated at Winchester and at Christ Church, Oxford. His poem, *The Splendid Shilling* (first authoritative edition, 1705), was called by Addison in *The Tatler* (No. 249) "the finest burlesque poem in the British language." Robert Harley and Henry St. John commissioned him to write a Tory counterblast (*Blenheim*, 1705) to Joseph Addison's *Campaign*. *Cyder* (1708), one of the earliest of the great didactic poems of the 18th century, is modeled on the *Georgics* of Virgil. *Cerealia, an Imitation of Milton* (1706), although printed without his name, may safely be ascribed to him. Philips died at Hereford on Feb. 15, 1709.

See *The Poems of John Philips*, ed. by M. G. Lloyd Thomas (1927); Samuel Johnson in *The Lives of the Poets*, vol. i (1781).

PHILIPS, KATHARINE (1631–1664), English poet known to her contemporaries as the "Matchless Orinda," was born in London on Jan. 1, 1631. She married James Philips, a Welsh Puritan and parliamentary leader, in 1648. Her home in Cardigan, Wales, became the centre of a "society of friendship," the members of which were known by romantic pseudonyms, Mrs. Philips being Orinda; her friend Mrs. Anne Owen, Lucasia; her husband, Antenor; and Sir Charles Cotterell, Poliarchus. Henry Vaughan exchanged poetical compliments with her and Jeremy Taylor addressed to her *A Discourse of the Nature, Offices and Measures of Friendship* (1657). The atmosphere of the circle is preserved in *The Letters of Orinda to Poliarchus* (1705). Her *Pompey* (1663), a translation from Corneille, was successfully acted and

her poems appeared in a pirated edition (1664). An authentic edition by Sir C. Cotterell appeared in 1667. She died of smallpox in London on June 22, 1664.

Orinda's poems represent a transition from the old courtly poetry to the Augustan manner of the Restoration. One of her lyrics was praised by Keats and she wrote the heroic couplet with skill and dignity. *The Letters to Poliarchus* are lively and spirited.

The poems were edited by G. Saintsbury in his *Minor Poets of the Caroline Period,* vol. 1 (1905). *See* also P. W. Souers, *The Matchless Orinda* (1931). (V. DE S. P.)

PHILIPS, PETER (1561–1628), important English composer of madrigals, motets, and keyboard music. He was a Roman Catholic, and in 1582 he left England for Italy, where he became organist of the English College in Rome. In 1585 he entered the service of Thomas, Lord Paget, with whom he traveled extensively. After Lord Paget's death in 1590 Philips went to Antwerp, and in 1597 he finally moved to Brussels, where he was appointed organist of the royal chapel of the archduke Albert of Austria. In 1593 he was accused by the Dutch authorities of planning the murder of Queen Elizabeth I, but after imprisonment and trial he was released. He probably took holy orders, for in 1610 he was appointed to a canonry. He died in Brussels in 1628.

Philips published volumes of his own madrigals, to Italian texts, in 1596, 1598, and 1603. Eight volumes of his church music were published between 1612 and 1633. A posthumously published volume of Masses is lost. Philips evidently enjoyed a considerable reputation during his lifetime, for many of his compositions appeared in contemporary collections, including Thomas Morley's *First Book of Consort Lessons* (1599) and the *Fitzwilliam Virginal Book,* which contains 19 keyboard pieces by him. Philips' style reveals Italian and Dutch as well as English traits; J. P. Sweelinck was a powerful influence, and his firm polyphonic passages are at times reminiscent of William Byrd. (DA. C. B.)

PHILISTINES, a people of Aegean origin who occupied the southern coast of Palestine during the 12th century B.C.

History.—According to biblical tradition (Deut. 2:23; Jer. 47:4; etc.) they came from Caphtor (Crete), but there is no archaeological indication of a Philistine occupation of the island. The name occurs for the first time, in Egyptian records, as *prst* among the second wave of the "Peoples of the Sea" who invaded Egypt during the eighth year of Ramses III (*c.* 1190 B.C.) after ravaging Asia Minor, Cyprus, and Syria (*see* SEA PEOPLES). These peoples were displaced from their original homelands as part of the extensive population movements of the latter half of the 2nd millennium B.C. After being repulsed by the Egyptians they occupied the coastal plain of Palestine from Joppa to the Wadi Ghazzeh. This area contained the five cities (the Pentapolis) of the Philistine confederacy (Gaza, Ascalon [Ashkelon], Ashdod, Gath, and Ekron; *qq.v.*) and was known as Philistia or the Land of the Philistines. It was from this designation that the whole of the country was later called Palestine by the Greeks. In Gen. 21:32, 34 and Ex. 13:17; 15:14; 23:31 the references to Philistia and the Philistines are anachronistic.

After settling on the coast, perhaps with Egyptian permission, the Philistines expanded into neighbouring areas and soon came into conflict with the Israelites, also recently arrived in the country. The Samson saga (Judg. 14–16) reflects this period. Due to their superior arms and military organization the Philistines were able (*c.* 1050) to occupy part of the Judaean hill country and to crush resistance at Ebenezer, destroy Shiloh, and capture the Ark (I Sam. 4:1–10). Archaeological evidence has shown that they devastated part of western Palestine. Saul was able to repel the Philistines (*c.* 1020), but their resurgence is shown by the Goliath story (1 Sam. 17) and the account of David's victories over them. After becoming king, David, using his intimate knowledge of their tactics, was able to defeat and subjugate the Philistines. They were reduced to a secondary role, and their history thereafter is that of the individual cities rather than of a people. After the division of Judah and Israel (*c.* 934 B.C.) the Philistines regained their independence and were often engaged in border battles with the Judahites and Israelites (I Kings 15:27; etc.).

The first nonbiblical reference to the Philistines after their settling on the Palestinian coast is in the annals of the Assyrian king Adad-nirari III (810–782), who boasted of having collected tribute from Philistia (Palastu). In the later Assyrian period the Philistine cities were involved in pro- and anti-Assyrian intrigues and suffered from Tiglath-pileser III (734), Sargon (720, 713, 712), and Sennacherib (701). Excavations in 1963 revealed fragments of a victory stele of Sargon set up in Ashdod. In the 7th century Gaza, Ashkelon, Ekron, and Ashdod were vassals to the Assyrian rulers Esarhaddon and Ashurbanipal. The city of Gath seems to have come under the dominance of nearby Ashdod.

During the later part of the century the Philistine cities were vassals to Egypt. An Aramaic papyrus from Saqqarah (Egypt) records the plea of a Philistine ruler to his Egyptian overlord for help against Nebuchadrezzar of Babylon. With the conquests of Nebuchadrezzar in Syria and Palestine, the Philistine cities became part of the Neo-Babylonian Empire. They were to remain part of the Persian Empire. During the Greek and Roman periods they were typical Hellenistic cities.

Culture and Religion.—There are no documents in the Philistine language, and the only Philistine word that can be positively identified is *seranim,* "lords," which is to be equated with Greek *turannos,* a word of Asianic origin. They were uncircumcised—their only known cultural trait—for which they were despised by the Israelites (Judg. 14:3; 15:18; I Sam. 17:26; 18:25). Very little is known of the Philistine religion since all their gods known from biblical and other sources have Semitic names—Dagon, Ashtaroth, Beelzebub (for Ba'al Zebul), and Marnas—and were surely borrowed from the conquered Canaanites. It is also most likely that Canaanite and then Aramaic gradually became the languages of Philistia, as Greek did during the Hellenistic period. Until their defeat by David the Philistine cities were ruled by *seranim,* who acted in council for the common good of the nation. After their defeat, the *seranim* were replaced by kings.

The Philistines in their period of expansion were able to muster large numbers of well-armed and well-trained troops. The Philistine warrior wore an Aegean kilt and a plumed headdress, and like Goliath was armed to the teeth and engaged in single combat (I Sam. 17:5–7). The Philistines held for some time a monopoly on smithing iron (I Sam. 13:19–22), a skill probably acquired in Asia Minor. At sites occupied by the Philistines at an early period, a distinctive type of ceramics, a variety of 13th-century Mycenaean styles, is found. This "Philistine" pottery went out of use during the 10th century. At some sites anthropoid clay coffins are also found in conjunction with this pottery.

The use of the term Philistine for a person deficient in liberal culture and enlightenment, whose chief interests are material, prosaic, and commonplace, arose in the mid-19th century. In the early 19th century German students applied the epithet *Philister* to those who had not received a university training and who were therefore considered uncultured. English writers, such as Carlyle and Arnold, took over the term and made it popular. It is now often used for those who oppose innovations in the arts.

PHILISTUS (*c.* 430–356 B.C.), Greek historian of Sicily, born at Syracuse *c.* 430 B.C., helped Dionysius I to seize power (405), and became his right-hand man and commander of the citadel, till he was exiled (386/385) for reasons now obscure. Recalled after 20 years by Dionysius II at the time of Plato's first visit to his court, he held high command first in the Adriatic and later at home in the civil war, and died on active service when over 70 (356). During his exile, spent mostly in Epirus, he began his

history, which attained ultimately to 13 books, 7 on Sicilian affairs before 405, 4 on the reign of Dionysius I, and 2 on the early years of Dionysius II (367–363). (It was continued by the Syracusan Athanas.) Though the scanty surviving fragments do not illustrate why Cicero called Philistus "almost a miniature Thucydides," his book clearly became a standard work, used not only by Ephorus in his Sicilian sections but also by Timaeus and Plutarch, writers who disliked his pro-monarchical point of view.

PHILLIP, ARTHUR (1738–1814), British admiral, the first governor of New South Wales, was born in London on Oct. 11, 1738. Educated at Greenwich, he became a midshipman in the navy in 1755 and saw service in the Mediterranean and in the West Indies, where he was promoted lieutenant (1762). Retired on half-pay in 1763, he was a farmer for the next 13 years. He then fought with the Portuguese Navy in its war against Spain, but the outbreak of war between England and France in 1778 caused him to return to England. In 1786 he was assigned the duty of taking several ships out to Australia to form a convict settlement. The "first fleet," which set sail on May 13, 1787, consisted of 11 ships, ill-equipped despite Phillip's great efforts to obtain essentials for a settlement. After much difficulty, Phillip brought his ships first to Botany Bay (Jan. 18, 1788) and then to Port Jackson. Hampered by mutinous troops, by convicts unable or unwilling to work, and—until the middle of 1790—by the threat of famine, Phillip and a few of his officers were able to establish a settlement through their energy, humanity, and example. Phillip permanently inspired the settlement and put it on the road to becoming a colony. He left Australia on Dec. 11, 1792, and his resignation was accepted after his arrival in England in 1793. He saw further action at sea (1796–98) and was promoted rear admiral (1801), vice admiral (1809), and admiral (1814). He died at Bath on Aug. 31, 1814. *See* also Australia, Commonwealth of: *History.*

PHILLIPPS DE LISLE, AMBROSE LISLE MARCH (1809–1878), a leading figure in the 19th-century Roman Catholic revival in England, was born at Garendon Park, Leicestershire, on March 17, 1809, the elder son of Charles March Phillipps; he took the name De Lisle in 1862 from his paternal grandmother's family, then without heir. Converted to Roman Catholicism from evangelical Anglicanism at the age of 16, he founded in 1835 the first post-Reformation English Trappist monastery, called Mount St. Bernard, presenting an estate in Charnwood Forest, Leicestershire, to a group of monks from Ireland.

He wrote a number of religious works and was the benefactor of other religious communities, the supporter of the Gothic revivalism of A. W. N. Pugin (*q.v.*), a friend of leading figures of the Oxford Movement, and an overoptimistic worker for the corporate reunion of the churches. He died at Garendon on March 5, 1878.

See E. S. Purcell, *Life and Letters of Ambrose Phillipps De Lisle,* 2 vol. (1900). (M. Dk.)

PHILLIPS, EDWARD (1630–1696?), English writer and biographer of Milton, who was his uncle, was born in London in Aug. 1630. His father, who died in 1631, was Edward Phillips of the crown office in chancery, and his mother was Milton's only sister, Anne. Edward and his younger brother John were educated by Milton, in whose house they boarded and studied the classics, mathematics and music. Edward entered Magdalen Hall, Oxford, in Nov. 1650, but left in 1651 to be a bookseller's clerk in London. He was tutor to John Evelyn's son (1663–65), and, later, in the families of Lord Herbert and the earl of Arlington. His interesting memoir of Milton (1694) is prefixed to his translation of Milton's *Letters of State.* John Aubrey states in his *Minutes of Lives* that all the poet's papers came into his nephew's hands. His other works include *A New World in Words, or a General Dictionary* (1658), which ran through many editions; an edition (1660–62) of Sir Richard Baker's *Chronicle of the Kings of England,* with the section on 1650–58 showing a strong royalist slant; and *Theatrum Poetarum* (1675), a list of great poets, principally English ones, with critical notes and a prefatory *Discourse of the Poets and Poetry* which may have been written by Milton. He also added a supplement (1676) to John Speed's *Theatre of Great Britain,* and wrote *Enchiridion linguae latinae* (1684), said to be based on Milton's notes. The date of his death is unknown, but his last book is dated 1696.

His brother John Phillips (1631–1706) has been proved to be the author of a biography of Milton which was long thought anonymous. He appears to have acted as Milton's secretary, and in 1652 published a Latin reply to the anonymous attack on the poet entitled *Pro Rege et populo anglicano.* In 1655 he wrote a bitter attack on Presbyterianism, *A Satyr Against Hypocrites,* much in line with Milton's disapproval of the sect. In 1656 he was summoned before the privy council for his share in a book of licentious poems, *Sportive Wit* (1656), which was suppressed, but only to be replaced by another, *Wit and Drollery* (1656). John Phillips was a voluminous writer, often obscene, but entertaining.

See W. Godwin, *Lives of Edward and John Phillips* (1815); H. Darbishire, *The Early Lives of Milton* (1932).

PHILLIPS, STEPHEN (1864–1915), English poet, playwright, and actor, who achieved a brief but brilliant success as a verse-dramatist in the Edwardian theatre, was born at Summertown, Oxford, on July 28, 1864, the son of a canon of Peterborough. He was educated at Trinity College School, Stratford-Upon-Avon, and at King's School, Peterborough, and was recommended for a scholarship at Queen's College, Cambridge, but did not take up residence. In 1885 he joined F. R. Benson's company as an actor and for some ten years played various parts, including Prospero in Shakespeare's *The Tempest,* but his chief accomplishment in Benson's eyes was that of a "first-class bowler of accurate length and varied pace." He had poetic gifts as well, and the publication of his *Poems* in 1897 launched his career as a poetic dramatist. Three of his verse-dramas were produced by Beerbohm Tree at His Majesty's Theatre: *Herod* (Oct. 31, 1900), *Ulysses* (Feb. 1, 1902), and *Nero* (Jan. 25, 1906). With J. Comyns Carr he also prepared for Beerbohm Tree a version of *Faust* performed on Sept. 5, 1908.

His most successful play was *Paolo and Francesca,* produced by George Alexander at the St. James's Theatre on March 6, 1902, which was rapturously received, its author being compared to Shakespeare. In fact Phillips had a gift for picturesque language and effective situations but little more, and his reputation withered, even in his own short lifetime. His last plays to be produced were *The Sin of David* at the Savoy Theatre on July 9, 1914, and *Armageddon,* staged by Martin-Harvey at the New Theatre on June 1, 1915. Phillips proved unable to withstand sudden success and gradual failure. His final years were ruined by excess and he died, penniless, at Deal, Kent, on Dec. 9, 1915.

See J. C. Trewin, *Benson and the Bensonians* (1960). (Ge. R.)

PHILLIPS, WENDELL (1811–1884), major U.S. abolitionist, orator, and reformer, was born in Boston, Mass., on Nov. 29, 1811. After graduating from Harvard College in 1831 and from Harvard Law School in 1834, he opened a law office in Boston but soon became active in the antislavery movement. In 1837 he married Ann Terry Greene, a fervent disciple of the noted abolitionist editor William Lloyd Garrison, and thereafter Phillips collaborated closely with Garrison. He lectured for antislavery societies, wrote editorials and pamphlets, and contributed financially to abolition enterprises. Public recognition as an orator came to Phillips in 1837, chiefly after his dramatic impromptu speech at Faneuil Hall in Boston denouncing the murder of the abolitionist editor Elijah P. Lovejoy in Alton, Ill. He was one of the most eloquent orators of the day and introduced to the U.S. public platform a direct and colloquial manner of speaking.

Sacrificing social status and a prospective political career, Phillips devoted himself to the unpopular cause of the slave. As a reform crusader, however, he refused to link abolitionism with political action. Like Garrison, he condemned the U.S. Constitution for its compromises over slavery and he advocated disunion

rather than association with slave states. He opposed the annexation of Texas and the Mexican War. During the Civil War he assailed Lincoln's unwillingness to uproot the institution of slavery, and after emancipation he contended that the Negroes should be guaranteed full civil rights. In 1865 he broke with Garrison over the discontinuance of the American Antislavery Society; and, after Garrison resigned, he served as its president until the organization disbanded in 1870.

Phillips was also a temperance advocate and a champion of women's rights. After the Civil War he continued his mission of moral education, advocating universal suffrage, labour reforms, prohibition of alcoholic beverages, prison reform, and issuance of paper money (*see* GREENBACKS). In 1870, in a brief and futile political episode, he was the gubernatorial candidate in Massachusetts of the Labor Reform Party and the Prohibition Party. Thereafter Phillips remained active on lyceum circuits until the 1880s, giving popular lectures on a number of noncontroversial subjects. He died in Boston on Feb. 2, 1884.

See Oscar Sherwin, *Prophet of Liberty* (1958); Lorenzo Sears, *Wendell Phillips* (1909). (R. J. Z.)

PHILLIPSITE, a mineral of the zeolite group, is a hydrated potassium, calcium and aluminum silicate. Like other natural and synthetic zeolites its unique crystalline make-up and structural porosity make it possible for the mineral to lose and regain water reversibly with little or no change in fundamental structure. Like other zeolites it has the property of exchanging electrically charged atoms (ions) with other substances. (For discussion of these properties *see* ZEOLITE.) Phillipsite is a mineral of secondary origin and occurs with other zeolites in cavities in basic volcanic rocks (basalts and phonolites); in red clay and deep sea deposits; and is formed from some hot spring waters. It has been found near Rome, Italy, in France, Germany and Australia, near Melbourne, and at the Giant's Causeway, County Antrim, N.Ire. The composition of phillipsite approximates $(K_2,Ca)Al_2(SiO_3)_4{\cdot}4H_2O$. It varies somewhat in composition, the variety pseudophillipsite having the formula $(K_2,Ca)_2Al_4Si_5O_{18}{\cdot}9H_2O$. Crystals are monoclinic, but only complex cruciform twins are known. Spherical groups with a radially fibrous structure and bristled with crystals on the surface are not uncommon. The hardness is 4.5, and the specific gravity 2.2.

The species was named in 1825 after the English mineralogist William Phillips (1775–1828); it also has been called christianite after Christian VIII of Denmark.

PHILLPOTTS, EDEN (1862–1960), English novelist, poet and dramatist, was born at Mount Abu, Rajputana, India, Nov. 4, 1862, and educated at Plymouth. A clerk for ten years in an insurance office, he then studied for the stage, but became a writer, producing over 100 novels, many of them with a Devonshire setting. Among his more important works are the novels *Children of the Mist* (1898); *Sons of the Morning* (1900); *Widecombe Fair* (1913); studies of boyhood and adolescence, *The Human Boy* (1899); *The Waters of Walla* (1950); plays, *The Farmer's Wife* (1917); *Yellow Sands* (with his daughter Adelaide, 1926); poems, *The Iscariot* (1912); *Brother Beast* (1928); *The Enchanted Wood* (1948); and *One Thing and Another* (poems and essays, 1954). He died at Broad Clyst, near Exeter, Dec. 29, 1960.

PHILLPOTTS, HENRY (1778–1869), English bishop, who combined efficient diocesan administration with vigorous and effective political controversy on almost every major issue in the mid-19th century, was born at Bridgwater on May 6, 1778, and educated at Corpus Christi College, Oxford. He was bishop of Exeter from 1831 until his death at Torquay on Sept. 18, 1869. An energetic high churchman and Tory, Phillpotts defended the Poor Law, the Test Act, the Peterloo incident (*see* PETERLOO), the Tory ministry's treatment of Queen Caroline and its policy toward Roman Catholic emancipation. He made a powerful attack on the Reform bill and on major ecclesiastical issues, including the foundation of the Anglican bishopric in Jerusalem (1841) and J. H. Newman's *Tract 90*. Unlike most Tories he opposed the Crimean War. Among various lawsuits in which he was involved, the most famous resulted in the Gorham judgment (1850), which overruled Phillpotts' refusal to institute G. C. Gorham to a living within his diocese on grounds of Gorham's unorthodox views on baptism. The Church of England owed much to Phillpotts' successful agitation for the revival of convocation.

See G. C. B. Davies, *Henry Phillpotts, Bishop of Exeter, 1778–1869* (1954).

PHILO, often called PHILO JUDAEUS (*c.* 30 B.C.–*c.* A.D. 40), Jewish philosopher, is the most important representative of Hellenistic Judaism, and his writings give us the clearest view of this development of Judaism in the Diaspora. He was probably a native of Alexandria, where he appears to have spent his whole life apart from one journey to Rome. His brother Alexander was alabarch or arabarch (*i.e.*, probably, chief farmer of taxes on the Arabic side of the Nile), from which it may be concluded that the family was influential and wealthy (Josephus, *Antiquities*, xviii, 8, 1). The only event of his life which can be actually dated belongs to A.D. 40, when Philo, then nearing the end of his years, went to Rome to persuade the emperor Caligula (Gaius) to abstain from claiming divine honour from the Jews. Of this embassy Philo has left a full account.

Philo appears to have been the greatest of all the Jewish philosophers of the Alexandrian School and has been called "the first theologian." His language is formed on the best classical models, especially Plato. He knows and often cites the great Greek poets, but his chief studies had been in Greek philosophy. His system was eclectic, but the borrowed elements are combined into a new unity with so much originality that he may fairly be regarded as representing a philosophy of his own, which has for its characteristic feature the constant prominence of a fundamental religious idea.

Philo's closest affinities are with Plato, with the later Pythagoreans and with the Stoics. Yet with all this Philo remained a Jew, and a great part of his writings is expressly directed to recommend Judaism to the respect and, if possible, to the acceptance of the Greeks. He was not a stranger to the specifically Jewish culture that prevailed in Palestine; in Hebrew he was not proficient, but he had evidently made some study of that language. His method of exegesis is similar in form to that of the Palestinian rabbinic scholars, and there are coincidences in matter. Philo recognized the Mosaic Scriptures of the Pentateuch as of absolute divine authority and as containing all truth. The other Jewish Scriptures he also recognized as prophetic (*i.e.*, as the writings of inspired men) but he did not place them on the same lines with the Law: everything that is right and good in the doctrines of the Greek philosophers had already been quite as well, or even better, taught by Moses. Thus, since Philo had been deeply influenced by the teachings of Greek philosophy, he found in the Pentateuch everything which he had learned from the Greeks. From these premises he assumed as requiring no proof that the Greek philosophers must in some way have drawn from Moses, a view which had already been expressed by Aristobulus. These presuppositions were maintained by an allegorical interpretation of Scripture. With its aid he discovered indications of the profoundest doctrines of philosophy in the simplest stories of the Pentateuch. This method of allegory is borrowed from the Stoics.

Theology.—Philo's doctrine of God starts from the idea that God is a being absolutely bare of quality, excluding any composition of body and soul, or of the four elements, or of substance and accidental quality, or of matter and form. No limitation can be predicated of God, who is eternal, unchangeable, simple substance, free, self-sufficient, better than the good and the beautiful. To predicate any quality of God would be to reduce him to the sphere of finite existence. Of him we can say only *that* he is, not *what* he is; and such purely negative predications as to his being appear to Philo, as to the later Pythagoreans and to the Neoplatonists, to constitute the only way of securing his absolute elevation above the world.

A consistent application of Philo's abstract conception of God would exclude the possibility of any active relation of God to the world, for a being absolutely without quality and movement cannot be conceived as actively concerned with the multiplicity of individual things. In fact Philo does teach that the absolute perfection, purity, and loftiness of God would be violated by direct contact with imperfect, impure, and finite things. But the pos-

sibility of a connection between God and the world is reached through a distinction which forms the most important point in Philo's theology and cosmology; the proper being of God is distinguished from the infinite multiplicity of divine ideas or forces: God himself is without quality, but he disposes of an infinite variety of divine forces, through whose mediation an active relation of God to the world is brought about.

Philo's conception of the nature of these mediating forces was self-contradictory. On the one hand they are nothing else than ideas of individual things conceived in the mind of God and, as such, ought to have no other reality than that of immanent existence in God; and so Philo says expressly that the "intellectual world" or totality of ideas is simply the Logos (*q.v.*) or Reason of God as Creator. Yet, on the other hand, these forces are represented as daemons or angels, hypostases distinct from God, individual entities existing independently and apart from him. This vacillation, however, as E. Zeller and others have justly remarked, is necessarily involved in Philo's premisses, for, on the one hand, it is God who works in the world through his ideas, and therefore they must be identical with God; but, on the other hand, God is not to come into direct contact with the world, and therefore the forces through which he works must be distinct from him.

The same inevitable amphiboly dominates in what is taught as to the supreme Idea or Logos. Philo regards all individual ideas as comprehended in one highest and most general idea or force—the unity of the individual ideas—which he calls the Logos or Reason of God and which is again regarded as operative Reason. The Logos, therefore, is the highest mediator between God and the world, the firstborn son of God, the archangel who is the vehicle of all revelation and the high priest who stands before God on behalf of the world. Through him the world was created, and so he is identified with the creative Word of God in Genesis (the Greek *logos* meaning both "reason" and "word"). Here again, we see, the philosopher is unable to escape from the difficulty that the Logos is at once the immanent Reason of God, and yet also a hypostasis standing between God and the world.

The whole doctrine of this mediatorial hypostasis is a strange intertwining of very dissimilar threads; on one side the way was prepared for it by the older Jewish distinction between the Wisdom of God and God himself, of which we find the beginnings in Job (28:12 *et seq.*) and in Proverbs (chapters 8 and 9) and the fuller development in Ecclesiasticus and in the Book of Wisdom, the last of which comes very near to Philo's ideas if we substitute for the term "wisdom" that of (divine) "reason." The Stoic teacher Poseidonius had already identified the Platonic ideas with the Stoic Logos. Philo goes a step further by placing the ideas in the Mind of God; but he makes it clear that they represent only God's relation to the world, not his essence.

The world and creation, in Philo's doctrine, rest on the presupposition of an absolute metaphysical contrast between God and the world. The world can be ascribed to God only insofar as it is a cosmos or orderly world; its material substratum is not even indirectly referable to God. Matter is a second principle, but in itself an empty one, its essence being a mere negation of all true being. It is a lifeless, unmoved, shapeless mass, out of which God formed the actual world by means of the Logos and divine forces. Strictly, the world is only formed, not created, since matter did not originate with God.

Ethical Teaching.—Philo's doctrine of man is also strictly dualistic and is mainly derived from Plato. Man is a twofold being, with a higher and a lower origin. Of the pure souls which fill airy space, those nearest the earth are attracted by the sensible and descend into sensible bodies; these souls are the Godward side of man. But on his other side man is a creature of sense, and so has in him a fountain of sin and all evil. The body, therefore, is a prison, a coffin, or a grave for the soul which seeks to rise again to God. The highest maxim of Philo's ethics is therefore deliverance from the world of sense and the mortification of all the impulses of sense.

In carrying out this thought, Philo differs from the Stoics. The Stoics cast man upon his own resources; Philo points him to the assistance of God, without whom man, a captive to sense, could never rise to true wisdom and virtue. Even in this life the truly wise and virtuous is lifted above his sensible existence and enjoys in ecstasy the vision of God, his own consciousness sinking and disappearing in the divine light. Beyond this ecstasy there lies but one further step, viz., entire liberation from the body of sense and the return of the soul to its original condition; it came from God and must rise to him again. But natural death brings this consummation only to those who, while they lived on earth, kept themselves free from attachment to the things of sense: all others must at death pass into another body. Transmigration of souls is in fact the necessary consequence of Philo's premisses.

Works.—The titles of the numerous extant writings of Philo present at first sight a most confusing multiplicity. More than three-fourths of them, however, are really mere sections of a small number of larger works. Three such great works on the Pentateuch can be distinguished.

1. The smallest of these is the *Zetemata kai lyseis* ("Questions and Solutions"), a short exposition of Genesis and Exodus, in the form of question and answer. The work is cited under the Greek title by Eusebius and by later writers, but the Greek text is almost wholly lost, and only about one-half is preserved in an Armenian translation. Genesis seems to have occupied six books. Eusebius tells us that Exodus filled five books. In the Armenian translation, edited by the Mekhitarist monk J. B. Aucher (1826), are preserved four books on Genesis and two on Exodus, but with lacunae. A Latin fragment, about half the fourth book on Genesis, was first printed at Paris in 1520. Of the Greek text there are numerous but short fragments in various ancient anthologies. The interpretations in this work are partly literal and partly allegorical.

2. Philo's most important work is the *Nomon hieron allegoriai* ("Allegories of the Sacred Laws"), a vast commentary on Genesis, dealing with chapters 2, 3, and 4 verse by verse and with select passages in the later chapters. The readers in view are mainly Jews, for the form is modeled on the rabbinic Midrash. The main idea is that the characters which appear in Genesis are properly allegories of states of the soul. All persons and actions being interpreted in this sense, the work as a whole is a very extensive body of psychology and ethics.

3. A work of a very different kind is the group of writings expounding the "Mosaic Law for Gentiles." These, in spite of their diverse contents, present on nearer examination indubitable marks of close connection. In them Philo seeks to give an orderly view of the chief points of the Mosaic legislation in the Pentateuch and to recommend it as valuable to gentile readers. The method of exposition is somewhat more popular here than in the allegorical commentaries, for, though that method of interpretation is not wholly excluded, the main object is to give such a view of the legislation as Philo accepted as historical. This work has three main divisions: (1) the interpretation of the first two chapters of Genesis, *Peri Moyseos kosmopoiias* (Lat. *De opificio mundi*), as Moses put his account of the Creation at the beginning of the Pentateuch in order to show that his legislation was conformed to the will of nature and that therefore those who followed it were true cosmopolitans; (2) the "Lives of the Wise," biographies of the three righteous men, Abraham, Isaac, and Joseph—being, so to speak, the living unwritten laws which, unlike written laws, present the general types of moral conduct; and (3) legislation proper, in two subdivisions, (*a*) the ten principal chapters of the law and (*b*) the special laws belonging to each of these ten. An appendix adds a view of such laws as could not be brought under the rubrics of the decalogue.

4. Of the miscellaneous writings attributed to Philo, some appear to have survived in their entirety, some are extant only in translation or in fragments and some have been held to be spurious. The Greek texts of the three books "On the Life of Moses" and of the treatise "On Nobility" have been preserved. Two of five books on the affairs of the Alexandrian Jews also survive in Greek: namely, "Against Flaccus," in which Philo relates how the governor Flaccus, early in Caligula's reign, allowed the mob to persecute the Jews in Alexandria; and *Peri areton kai presbeias pros Gaion* (Lat. *De legatione ad Gaium*), in which he describes the persecution following Caligula's demand for divine honours and recounts his embassy to Rome to seek relief for the Jews of Alexandria.

Of the two books "On Providence," the title of which is twice mentioned by Eusebius, we possess only an Armenian version edited with Latin translation by J. B. Aucher (1822); book i appears moreover to be in a Christian recension. Also in Armenian, except for two small fragments preserved in the *Florilegium* (anthology) of Leontius and Johannes, is the surviving text of Philo's *Alexandros* ("Alexander, or That Dumb Animals Have Reason"), mentioned both by Eusebius and by Jerome. Eusebius (*Praeparatio Evangelica*, viii, 6, 7, 11) preserves fragments of the *Hypothetika* and of a "Defense of the Jews," the latter being presumably identical with the work "On the Jews" that he mentions elsewhere.

The authenticity of the treatise "That Every Righteous Man Is Free" was disputed by Z. Frankel and by R. Ansfeld but was defended by Paul Wendland, who believed it to be an early work of Philo's. The Philonic origin of the document on the Therapeutae, *Peri biou theoretikou* (Lat. *De vita contemplativa; see* JEWISH SECTS DURING THE SECOND COMMONWEALTH) was also disputed, notably by P. E. Lucius in *Die Therapeuten* (1879), but was ably defended by L. Massebieau in the *Revue de l'histoire des religions*, xvi (1887), by F. C. Conybeare in *Philo About the Contemplative Life* (1895), and by Wendland in *Die Therapeuten* (1896). Against J. Bernays and others who denied Philo's authorship of the treatise "On the Incorruptibility of the World"—apparently one of the sources from which the suppositious treatise "On the World" was compiled—F. C. Cumont's vindication, *Philo de aeternitate mundi* (1891) may be consulted. Two discourses extant only in Armenian, one on Samson, the other on Jonah, are inauthentic. *See* also references under "Philo" in the Index.

BIBLIOGRAPHY.—Editions of Philo's works include those by T. Mangey, 2 vol. (1742); by L. Cohn, P. Wendland and S. Reiter, 7 vol. (1896–1930); and by F. H. Colson and G. H. Whitaker, 9 vol., with Eng. trans. and supplement, Loeb Series (1929–53).

(E. Sc.; C. Bi.; A. An.)

PHILOCTETES, Greek legendary hero who played a decisive part in the final stages of the Trojan War. The son of Poeas, he held sway over a group of cities on the southeastern Thessalian seaboard. He (or his father) had been bequeathed the bow and arrows of Heracles in return for lighting his funeral pyre; Philoctetes became a famous archer. En route for Troy he was incapacitated by the bite of a water snake and was left behind by the Greeks on the island of Lemnos. A prophecy of Helenus revealed that Troy could only be taken with the aid of Heracles' bow and arrows. Accordingly Odysseus and Diomedes went to Lemnos and persuaded Philoctetes to accompany them to Troy. There he was healed of his wound by Machaon, and killed Paris in single combat, thus paving the way for the city's fall. He subsequently returned home safely, but wandered as a colonist to southern Italy, where he ultimately met his end in battle. Homer gives only a skeleton outline of this story; the details were filled in by later epic writers. All three of the great Attic tragedians handled the theme, but Sophocles' *Philoctetes* alone survives. In it Achilles' young son Neoptolemus accompanies Odysseus, and the dilemma of his divided loyalties to the Greeks and to the tormented hero is resolved only through the direct intervention of Heracles. Philoctetes is sympathetically portrayed—a symbol of a man triumphing over pain and through suffering (*see* SOPHOCLES: *His Tragic Thought: Philoctetes and Oedipus Coloneus*).

See Pauly-Wissowa, *Real-Encyclopädie der classischen Altertumswissenschaft*, vol. 19, col. 2500–09 (1938). (D. E. W. W.)

PHILODEMUS (*c.* 110–40 B.C.), Greek poet and Epicurean philosopher (*see* EPICURUS) who did much to spread that doctrine among Roman men of letters, was born at Gadara near the Sea of Galilee. After studying at Athens under the Epicurean Zeno of Sidon, he became the mentor of a Roman of high rank, L. Calpurnius Piso, with whom he lived in the vicinity of Naples. Horace is thought to have been much influenced by him. Cicero implicates Philodemus in a personal attack on Piso in his speech *In Pisonem* but knew his writings well and used them as a source for Epicurean doctrine. Of his poems, 34 epigrams are extant; these consist of light verse, not linked with his philosophy. Treatises by Philodemus predominate among the books of the great Epicurean Library discovered at Herculaneum; the library itself may have belonged to him, the house to Piso or to his heirs. Much of what Philodemus says evidently comes from Zeno of Sidon; but he gives glimpses of controversies between the later Epicureans and their opponents, and among themselves. (D. J. A.)

PHILODENDRON, the generic and common name for about 200 species of plants of the aroid family (Araceae; *q.v.*), many of which are prized as landscape ornamentals in moist, warm regions or as conservatory and house plants. They are native to tropical America, mostly in forests, and are valued for the gloss, sculpture, variegation and colour of their leaves. Most philodendrons are vining plants but some (*e.g.*, the "self-heading" horticultural varieties) are almost stemless, with leaves that arise from a crown. The leaf blades, which are relatively thick, vary in different species from heart-shaped to ovoid, from smooth-margined to deeply lobed and from a few inches to about three feet long; in some species the leaves are perforated, and in certain horticultural varieties they turn red in cool weather. The base of the leaf stalk, or petiole, clasps the stem. The flowers are small, without petals, and are crowded, with male above and female below, on a spikelike spadix enfolded by a leaflike spathe. The spathe, which is usually whitish, yellowish or red, persists around the cluster of berrylike fruits.

ROCHE

TWO OF THE MANY LEAF VARIATIONS OF PHILODENDRONS: (LEFT) PHILODENDRON RADIATUM (DUBIUM); (RIGHT) P. OXYCARDIUM (FLORIST'S P. CORDATUM)

As house plants, philodendrons require well-aerated soil and moderate light. They should be thoroughly watered only when the soil begins to feel dry to the touch. Daily spraying or weekly washing of the leaves with water is helpful. Stem cuttings root readily in water or in moist sand, peat moss, soil, etc. Vining philodendrons soon require support. When grown as house plants, philodendrons rarely blossom.

See also HOUSE PLANTS. (P. D. V.)

PHILOKALIA (DOBROTOLYUBIE), "Love of the Good and the Beautiful," a famous prose anthology of Greek monastic texts first printed in Venice in 1782 and quickly sold out in the Greek Orthodox world. It was edited by Bishop Makarios of Corinth and Nikodimos Hagioritis (Nicodemus the Athonite). The *Philokalia* was part of the movement for spiritual renewal in Greek monasticism, and Greek devotional life in general, by a return to Hesychast ideals (*see* HESYCHASM). Its great influence can be understood

only against the background of Hesychast teaching and mystical way of life. The 1,207 pages of the *Philokalia* consist of many long extracts from the desert fathers who since the 11th–12th century had been regarded by Byzantine monasticism as the forerunners of Hesychasm and from the Hesychast authors themselves: Simeon the New Theologian (*see* SIMEON, SAINT), Nicetas Stethatus (d. *c.* 1050), Nicephorus (2nd half of the 13th century), Gregory the Sinaite (1255–1346), Gregory Palamas (*see* PALAMAS, SAINT GREGORY), Ignatius and Callistus Xanthopulus (end of 15th century), etc.

The theme of the *Philokalia* is "inner asceticism," not merely outward obedience to one's superior or the practice of physical austerities. Inner asceticism means, above all, true repentance for one's sins, daily recollection of death and judgment, together with perpetual remembrance of God as omnipresent and omnipotent, and ceaseless prayer. A very important part is played by the "Jesus prayer," uttered in a particular bodily position with a special way of breathing.

The *Philokalia* had great success in the Slav countries, especially Russia, and a Church Slavonic version appeared in 1793 in St. Petersburg under the title of *Dobrotolyubie*. It was translated by the starets Paissy Velichkovsky, who introduced a neo-Hesychast spiritual renewal into Russian and Moldavian monasticism. Whereas in Greece the *Philokalia* apparently had little influence outside certain schools of monasticism (although attempts were made to reach a wider public with new editions in 1897 and 1957 ff.), the Church Slavonic version became through the influence of the startsi one of the favourite spiritual books of all classes of Russian laity during the 19th century. In 1877 Feofan Zatvornik (Theophanes the Recluse), former bishop of Tambov, made a Russian version in five volumes which altered the selection of extracts in a way that had been characteristic for Russian monasticism since the time of Nil Sorski in the 16th century. An interesting example of the influence of the *Philokalia* is seen in *Otkrovennye rasskazy strannika dychovnovy svoemu otsu* (1894), which was very popular in Russian and is now widely read in western Europe and America (Eng. trans., *The Way of a Pilgrim,* 1930, revised 1952, by R. M. French).

BIBLIOGRAPHY.—Partial Eng. trans. by E. Kadloubovsky and G. E. H. Palmer, *Writings from the Philokalia on the Prayer of the Heart* (1951), *Early Fathers from the Philokalia* (1954); partial French trans. by J. Gouillard, *Petite Philocalie de la prière du coeur* (1953). (F. v. L.)

PHILOLAUS (fl. in second half of 5th century B.C.), Greek philosopher of the Pythagorean School, was born at Tarentum or (according to Diogenes Laërtius viii, 84) at Crotona in southern Italy. After the death of Pythagoras great dissensions prevailed in the Italian cities. According to some accounts, Philolaus fled, taking refuge first in Lucania and then at Thebes, where he had Simmias and Cebes as pupils. Later Philolaus returned to Italy, where, it is said, he taught Archytas. He studied the Pythagorean number theory, particularly the properties inherent in the decad—the sum of the first four numbers, consequently the fourth triangular number, the *tetractys*. It is from a book of his that Plato's successor Speusippus is reported to have reproduced the doctrine. It would seem that Philolaus was the first systematizer of Pythagoreanism, but the evidence for this is a matter of dispute.

Pythagoras probably knew the construction of three of the regular solids, and Empedocles is stated to have been the first who maintained that there are four elements. Philolaus, connecting these ideas, held that the elementary nature of bodies depends on their form and assigned the tetrahedron to fire, the octahedron to air, the icosahedron to water, and the cube to earth; the dodecahedron he assigned to a fifth element, ether or the pure air surrounding the universe. The elements themselves seem to have been the product of number, and they existed in a harmony produced by the normal Pythagorean principles of Limit and the Unlimited. Similarly, in an animate body health consisted in a balance of the two further opposites, heat and cold. Philolaus regarded the soul as a "mixture and harmony" of the bodily parts; he also assumed a substantial soul, whose existence in the body is an exile because of sin, showing the religious outlook that Plato attributes to him in the *Phaedo* (61 D *ff.*). For the important astronomical theory sometimes attributed to him, *see* PYTHAGORAS AND PYTHAGOREANISM.

Both the astronomy and the physics which are credited to Philolaus have been held to be inadmissible before Plato's *Timaeus*. Certainly the discovery of how to construct the octahedron and the icosahedron is put after Philolaus' time on far better evidence. (And the only quotation about the five elements, it should be noticed, does not name the regular solids at all.) The man himself has even been considered a fanciful invention of Plato; and Erich Frank argued that his works were forged by Speusippus. If his genuineness is accepted, it is certainly necessary to be discriminating about the quotations which have survived and still more so about the descriptions of his doctrine made by ancient writers.

BIBLIOGRAPHY.—Ancient testimonies and fragments are collected by H. Diels and W. Kranz, *Fragmente der Vorsokratiker,* vol. i, 7th ed. (1954). For the case against their genuineness *see* E. Frank, *Plato und die sogenannten Pythagoräer* (1923); for a reply to Frank's arguments, E. Zeller, *La Filosofia dei greci,* Italian trans. ed. by R. Mondolfo, pt. i, vol. ii, pp. 367–382 (1938). PHILOLOGY, a term now rarely used but once applied to the study of language and literature. A human society is apt to be bound together by a single language, in which its entire cultural tradition, written and unwritten, is composed. As time goes by, the universe of tradition is seen to contain diverse subject matter, which for convenience of handling is classified broadly to correspond to the activities of the particular society—its law, religion, history, philosophy, for example. That part of tradition, the content of which is dominantly imaginative and the form artistic, excites its own interest and criticism and even devotion, for the sake of its better preservation and understanding: this was designated philology. Nowadays a clear distinction is made between literary and linguistic scholarship, and the term philology, where used, means the study of language. It survives in the titles of a few learned journals that date to the 19th century. *See* LINGUISTICS.

PHILOPOEMEN (*c.* 252–182 B.C.), Greek general of the Achaean League (*q.v.*), was born at Megalopolis, in Arcadia, and there trained to a career of arms by the Academic philosophers Ecdelus and Damophanes. When Cleomenes III of Sparta took Megalopolis (223), Philopoemen skilfully evacuated it, and his initiative at Sellasia (222) won the praise of Antigonus Doson, king of Macedonia. The next 11 years he spent as a condottiere in Crete; he returned to Achaea and was elected federal cavalry commander for 210/209, when his reorganized cavalry defeated the Aetolians on the Elean frontier. As general of the confederation for 208/207 he introduced heavier Macedonian armour and phalanx tactics, and so crushed the Spartans under Machanidas at Mantinea (207). This Achaean revival reduced Achaean dependence on Macedonia. General again in 206/205 and 201/200, he expelled Nabis of Sparta from Messene, and routed him at Tegea. But in the Second Macedonian War his policy of neutrality harmed him, and he returned to Crete until 193. In a fourth generalship (193/192) he failed against Nabis by sea, but almost annihilated his army near Gythium. The Roman general Flamininus prevented his taking Sparta, but on Nabis' assassination (192) he incorporated it in the confederation. Henceforth he dominated Achaean policy. He was general in 191/190 and 189/188; in 191, when trouble arose at Sparta, he closed the gates against both Diophanes, the Achaean general, and Flamininus, but in 188 he inflicted savage reprisals after a Spartan attack, and abolished the Lycurgan regime. This incurred Roman censure. He was again general in 187/186 and 183/182. When Messene rebelled, he was taken in a skirmish and given poison (182). Philopoemen's chief merit lies in his restoration of Achaean military efficiency. He was admired by Polybius, and by the unknown Roman in Plutarch who called him "the last of the Greeks"; but his general policy was narrow, and his constant assertion of Achaean rights alienated the Romans and prevented a collaboration that was inevitable from being also fruitful.

PHILOPONUS, JOHN (5th–6th century A.D.), a prolific writer of the philosophical school of Alexandria who, as an expositor and critic of Aristotle, exercised a deep influence on later generations. The name John marks him as a Christian, and there is no good ground for supposing him to have been a convert. Since his earliest studies were in language and literature, he styled himself "Grammaticus," and he was also known by the surname Philoponus (("industrious"), which seems to have been the class name of a group of active Christian laymen.

In philosophy John was a pupil of Ammonius Hermiae (*q.v.*). Among his works are several commentaries on treatises of Aristotle, which seem to be partly based on Ammonius' oral instruction. He frequently adopts, on religious grounds, a critical attitude toward Aristotle, which distinguishes him from other commentators of the age. His *De aeternitate mundi*, written in 529, which has survived almost complete, is a refutation of Proclus, who, with other Neoplatonists, supposed the heavens to be divine and imperishable; a philosophical defense is given of the view that the world was created by God from nothing and will be destroyed. The work, written when Christianity was in the ascendant at Alexandria, may have been designed to shield the Alexandrian school of philosophy. Besides this, John wrote a treatise, the general outline of which is known from the bitter retort made by Simplicius (*q.v.*), against certain principles of Aristotle's physical science. John's theological writings, in which he supported the Monophysites (*q.v.; Opuscula Monophysitica*, edited by A. Sanda, 1930), were condemned as heretical in 680. (D. J. A.)

PHILOSOPHY (ARTICLES ON). The article PHILOSOPHY provides a general introduction to the subject matter of philosophical inquiry. For an outline of the course that this inquiry has pursued in the western world *see* PHILOSOPHY, HISTORY OF. Parallel to the latter from the final period of antiquity are ARABIC PHILOSOPHY and JEWISH PHILOSOPHY. CHINESE PHILOSOPHY and INDIAN PHILOSOPHY are independent.

METAPHYSICS briefly indicates the type of inquiry traditionally included under this heading. For particular aspects *see*, for instance, ABSOLUTE; ANALOGY; BODY AND MIND; CAUSALITY; COSMOLOGY; DETERMINISM; DURATION AND TIME; FORM; FREE WILL; INFINITY AND THE INFINITE; LOGOS; PLURALISM AND MONISM; PREESTABLISHED HARMONY; QUALITIES; SUBSTANCE; and UNIVERSAL. KNOWLEDGE, THEORY OF, a key article, is supplemented by the following: BELIEF; EMPIRICISM; IDEA; INNATE IDEAS; INTUITION; PHENOMENALISM; RATIONALISM; SKEPTICISM; and TRUTH. A distinct group is formed by SCIENCE and SCIENTIFIC METHOD, together with INDUCTION and PROBABILITY, and the shorter HYPOTHESIS.

LOGIC and LOGIC, HISTORY OF, with SEMANTICS IN LOGIC, are supplemented by numerous articles including ABSTRACT AND ABSTRACTION; CATEGORY; CLASSIFICATION; CONVERSION (IN LOGIC AND MATHEMATICS); DEFINITION; EXPLANATION; FALLACY; MATHEMATICS, FOUNDATIONS OF; MEANING; NAME (IN LOGIC); PROPOSITION; SYLLOGISM; and THOUGHT, LAWS OF.

ETHICS; ETHICS, HISTORY OF and ETHICS, COMPARATIVE are supplemented by EGOISM; HEDONISM; and UTILITARIANISM. *See* also POLITICAL PHILOSOPHY. For history of that discipline *see* AESTHETICS, HISTORY OF; for modern developments *see* AESTHETICS.

For schools and individual systems of philosophy the following articles, in roughly chronological order, may be consulted; PYTHAGORAS AND PYTHAGOREANISM; ELEATIC SCHOOL; SOPHISTS; ACADEMY, GREEK; PERIPATETICS; CYRENAICS; CYNICS; STOICS; NEOPLATONISM; SCHOLASTICISM; CARTESIANS; CAMBRIDGE PLATONISTS; IDEALISM; TRANSCENDENTALISM; NEO-KANTIANISM; NEO-HEGELIANISM; POSITIVISM; PRAGMATISM; PHENOMENOLOGY; LOGICAL POSITIVISM; and EXISTENTIALISM.

Expositions of the thought of major philosophers will be found in the various biographical articles: ARISTOTLE; BERKELEY, GEORGE; and so on. For medieval philosophers particularly, where the name may be one of several forms, it is advisable to consult the Index first to determine the heading under which the biography is to be found. *See* also RELIGION (ARTICLES ON).

PHILOSOPHY is a word whose range of usages can scarcely be explained without some account of its history. It is derived from the composite Greek noun *philosophia* which means the love or pursuit of wisdom. Herodotus uses the corresponding verb *philosophein* when writing of Solon's travels in search of knowledge; and Thucydides puts it into the mouth of Pericles in his account of the famous funeral speech about the Athenian way of life. In these passages it suggests especially the attempt to satisfy curiosity, but *sophia*, like the English word "wisdom," implied not only wide knowledge but also sound judgment about the values of different things in life (*i.e.*, about what is most worth pursuing for its own sake) and even sometimes shrewdness in practical decisions; so that *philosophia* was in origin a very general word for the pursuit of mental excellence. Pythagoras is said to have been the first to call himself a philosopher (*philosophos*), but we know so little for certain about him that we cannot tell what nuances of meaning the word had in his usage. In the Platonic dialogues it is often used by Socrates to describe a man engaged in the sort of inquiry that he himself pursued; and there can be little doubt that the historical Socrates called himself a philosopher, while disclaiming the title of *sophos*, which was given traditionally to Solon and the other sages of antiquity. There is here the beginning of a specialized or technical usage of the word, and Plato's representation of Socrates has had so great an influence on western thought that philosophy is still thought of as a study which deals for the most part, though not exclusively, with the subjects of Plato's dialogues and proceeds by the Socratic method.

The earliest of the Greek thinkers whose names were afterward included in histories of philosophy recognized no divisions of knowledge. The records of their sayings contain material of all sorts, from speculations about the constitution of the world by condensation and rarefaction of a single stuff to reflections about forms of government, and from observations of eclipses to advice on the management of children. By the end of the 5th century B.C., however, arithmetic, geometry, astronomy and music had been recognized as distinct studies. They are the *mathemata*, or disciplines, from which the word "mathematics" is derived, and for a long time they retained their special position as the first of the special sciences; thus they were still grouped together as the *quadrivium* in the curriculum of seven liberal arts taught at the medieval universities. The historical Socrates seems to have had no more than an intelligent layman's appreciation of these studies, and we are told that he gave up speculation about the nature of the physical world in order to concentrate attention on the search for definitions of universal notions and especially of those notions that have to do with human conduct and human character. But in the dialogue of Plato called the *Republic* he is represented as saying that the mathematical studies are a necessary preliminary to philosophical training. According to the scheme of education outlined there, anyone who would be a philosopher must learn the interconnections of the various sciences that are commonly taught separately, and no one can hope to make progress who lacks the power of *synopsis* (*i.e.*, of seeing things together). But all this is preparatory to the understanding of a system in which all "forms" (*i.e.*, characters in which individual sensible things may participate) have their places determined by their relation to the supreme Form of the Good.

It is difficult to work out any really convincing development of the scheme suggested by Plato in this dialogue, where his thought seems to be most ambitious; and we may reasonably suspect that Plato himself was unable to produce any detailed formulation that satisfied him. For he had recourse on various occasions to various analogies and sometimes even used the language of mystical illumination. But there can be found here already a number of features which recur constantly in the work of those later writers who are commonly accounted philosophers and which may therefore be taken as marks of philosophical thought.

Plato's Four Marks of Philosophical Thought.—First, there is the notion of a study in which the various special sciences are to be related together and understood as parts of one system. In recent times the increase of knowledge has been so rapid that it is difficult if not impossible for anyone to be master of the whole of a science such as chemistry, and we have therefore much more reason than Plato ever had to be worried about the dangers of spe-

cialization in education. So long as our plans for counteracting these evils do not take us beyond the boundaries of a single science, such as chemistry, we do not think that they have any connection with philosophy; but if we are more ambitious and try to provide a conspectus of all the sciences, this seems to us still a philosophical enterprise. To make clear the distinction between the *a priori* and the empirical sciences and to show the relations within the latter group between the physical, the biological and the psychological sciences—these are philosophical tasks, whether or not they are performed by professional philosophers. So too is the clarification of notions of high generality such as that of causation. If, as in physics, the development of a science makes it necessary to raise questions about concepts of this level, the scientist who tries to answer them is conscious that he is engaged for the time being in philosophy. Sometimes, indeed, the word "philosophy" is used popularly to mean any formulation of very general basic principles for a practical activity, such as politics or strategy.

Second, there is a contrast between sensible appearance and intelligible reality. Only those are philosophers who "contemplate things as they are in themselves and as they exist ever permanent and immutable" and "set their affections on that which in each case really exists" (Plato, *Republic*, 479–480). According to Plato's account, the realm of appearance is the ordinary world of *genesis*, or happening, about which we can never have more than opinion, while the realm of intelligible reality is the timeless system of mathematical objects and of "forms" such as goodness and justice (*i.e.*, the realm of ideas in the original sense of the word "idea," from which our modern colloquial usage is derived through a long and devious history). In the thought of some later philosophers (*e.g.*, Leibniz, Kant and Hegel) the contrast of sensible appearance and intelligible reality is drawn in a different way, and it may therefore be objected that our second common trait is no more than a superficial resemblance in terminology. Yet, however it may be evaluated, the resemblance is there; it can be found in the works of Indian and Chinese philosophers, who have not been bewitched by the powerful magic of Plato's style, and also in the philosophical utterances of modern physicists, who are certainly not Plato's disciples, though subject to his influence, like all other men of western civilization.

Third, in Plato's writings there is the suggestion that there can be no finally satisfactory account of the system of the sciences which does not connect all reality with the Form of the Good by showing why it is best that things should be as they are. In the *Republic* he makes Socrates assert that the Form of the Good is the source both of being and of intelligibility. Almost certainly Plato did not wish to identify it with the god of whom he speaks in other places; but his language in this passage is like that of theists, and the intellectual satisfaction which he promises is like that which many later philosophers have hoped to furnish by relating all things to God. In Plato's argument the study which enables certain carefully selected guardians of his state to understand the system of "forms" by relating each to the Form of the Good is supposed to be also of the greatest practical importance because it enables the guardians to discern the best way of life for men and so to guide their fellow citizens aright; and again similar claims have been made by many later philosophers on behalf of their study. When men speak of a philosophy, they commonly mean a very general account of things which is likely to affect the outlook or emotional attitude of those who accept it (*e.g.*, by making them more contented or more confident) and also possibly to influence their conduct by making them prefer some course that they might otherwise have found uninteresting or even distasteful. In the West such claims have most often been made on behalf of systems which are in some way descended from Plato's, but talk of philosophy as a world view which affects practical life is to be found also among thinkers whom Plato would condemn as heretics (*e.g.*, among materialists of the Marxist persuasion). Nor is this surprising, since to most persons of any education "philosophy" still suggests the pursuit of wisdom.

Fourth, the intellectual insight of the philosopher-guardians in Plato's *Republic* is supposed to be gained by practice of a special method called dialectic. If we may judge by etymology, this word originally meant the art of discussion, but it was used by Zeno of Elea as a name for his own technique of establishing a conclusion by showing that the opposite thesis, put forward by a critic, led to self-contradiction. One of the difficulties in the interpretation of Plato's account of philosophy is to know whether he fully accepted Zeno's account of philosophical method and, if so, how in detail he thought this would help him to carry out his program. There is a less strict sense in which Socrates might be said to have practised dialectic when he asked his companions for definitions and then tested their suggestions for consistence with ordinary usage. In Aristotle's works an argument is called dialectical when it proceeds from commonly received opinions as distinct from premisses already known to be necessarily true. In later times, for example among the Stoics and again in the Middle Ages, the word "dialectic" was often used as a general name for logic; and later still it was applied by Hegel and Marx to a special pattern of development by thesis, antithesis and synthesis which they supposed to be characteristic of philosophical thought. Clearly there is room here for a great deal of misunderstanding, and we may suspect without much uncharitableness that a great deal of misunderstanding and muddle has in fact occurred. But it is safe to say that when philosophical method has been explicitly distinguished from the method of other studies it has commonly been held to consist in the clarification of concepts by a technique like Zeno's *reductio ad absurdum*.

"Natural Philosophy" and "Moral Philosophy."—Here, then, in Plato's work we can find four marks of that kind of thought which we in retrospect call philosophical. But it was a long time before the name "philosophy" came to be restricted in ordinary usage to such thought. In the work of Aristotle and his successors for many centuries it still covers all that now would be called science. When he required a name for the Platonic study, including his own criticism of Plato's theses, Aristotle called it "first philosophy"; but the collection of treatises which he wrote about it came to be called the *Metaphysics*, because it was placed "after the *Physics*" (*meta ta physika*) in the ordering of his works by his pupils. His other works were treatises on logic (though not under that name), physics, botany, animal anatomy and physiology, psychology, ethics, politics, rhetoric and poetics. For many centuries to come these treatises were regarded as sections in an encyclopaedia of philosophy; and, long after their authority had been attacked by thinkers of the Renaissance, the subjects of which they treated were still described as parts of philosophy. Apparently this usage continued in England when it had become obsolete in some other countries; at the beginning of the 19th century Hegel found it curious that opticians and the like should advertise themselves in English learned periodicals as "philosophical instrument makers." And even now there are survivals of the usage in the titles of certain old foundations: the *Philosophical Transactions* contain papers of all sorts submitted to the Royal Society; and there are professors of "natural philosophy" who are engaged in nuclear research.

When the term "natural philosophy," which is a rendering of Aristotle's "physics," was appropriated in the 17th century to the new natural science of Galileo and Newton, it became customary to use the phrase "moral philosophy" to cover not only the field of Aristotle's "ethics" and "politics" but also psychology and all the other traditional parts of philosophy except logic. When he published his first work in 1739, David Hume called it *A Treatise of Human Nature, Being an Attempt to Introduce the Experimental Method of Reasoning into Moral Subjects*. Except in such survivals as the name of the Moral Science faculty at Cambridge, the usage has now disappeared, but the explanation of its origin throws light on the development of men's conception of philosophy.

After the time of Aristotle, observational science was continued for a time in the Museum of Alexandria and in some of the medical schools, but it ceased to have any place in the curriculums of the philosophical colleges which existed side by side in Athens until the time of Justinian I. It is true that the Stoics and the Epicureans talked much of physics in their courses of instruction;

but they meant by "physics" speculative systems of cosmology not subject to empirical test, and the philosophers of each school valued their own system chiefly for the bearing that they thought it to have on the way in which men should think of themselves and of their destiny. Thus universal determinism was an important doctrine for the Stoics because it suggested to them an attitude of religious resignation such as that found in Cleanthes' *Hymn to Zeus;* and atomism (which was later to inspire great scientific discoveries) found favour with Epicureans such as Lucretius because it could be made to furnish arguments against superstition. When a young man of Cicero's age went to study philosophy in Athens, the lectures that he heard consisted mostly of arguments for a certain way of life. No intelligent man could find a sufficient guide in the public religion of the time, and an interest in philosophy was not a sign that a man was more unsettled than his neighbours but rather a sign that he was more serious. All the schools preached imperturbability (*i.e.*, the calm which we still call philosophical), but they differed in the accounts which they gave of the good life; and so it was, for example, no accident that under the Roman empire many great servants of the state belonged to the Stoic school.

The idea of philosophy which educated men of the 17th and 18th centuries got from their classical reading was that of a study concerned before all else with ends and duties; it was therefore not surprising that they called it moral philosophy when they wished to distinguish it from the new experimental science, then called natural philosophy. If they had read the works of the medieval schoolmen, they might perhaps have come to think of philosophy as something more ambitious; but they had no taste for the metaphysical subtleties of St. Thomas Aquinas or of Duns Scotus. Moreover, apart from all literary influences, there was a special reason why they should be interested at this time in moral philosophy. According to the new physics, nature was like a vast machine and all its parts, including living bodies, like smaller machines. If this was correct, how could men be held responsible for their behaviour? How indeed could purposive action of any kind be explained? Stoics and Epicureans had both said that all things were corporeal, but in their time such a declaration meant little more than a rejection of Platonism, because their natural philosophy was vague and undeveloped. Having said that souls consisted of a special sort of matter, they had been content to go on talking about their thoughts and actions in the usual way. Now such talk seemed silly, because men had come to think of matter as that which obeyed the laws of mechanics and this conception left no room for spiritual attributes. At this time there was therefore a great need for some account of human life which would show how talk of purpose and responsibility could be reconciled with talk of mechanical regularity, and the attempt to find such an account was not unreasonably called moral philosophy, though it included difficulties that had not worried the ancients.

Many of the books written to satisfy this need had titles such as *An Essay Concerning Human Understanding.* Sometimes the authors explained their choice by saying that they thought philosophy must begin with an examination of the faculties by which men acquire knowledge, but there were many who thought that a correct theory of knowledge would provide also an immediate solution of the problem about the status of minds and their connection with bodies. In their different ways Spinoza, Leibniz, Berkeley, Hume, Kant and Hegel all held this view of the task of philosophy. Dugald Stewart probably went too far when he wrote at the beginning of the 19th century for the *Encyclopædia Britannica* (8th ed., vol. i, p. 227) that a change in the pursuits of philosophers had so altered the meaning of the word "metaphysics" that it was now applicable to "all those inquiries, which have for their object to trace the various branches of human knowledge to their first principles in the constitution of our nature." But it is true that all philosophy other than natural science was thought to be concerned with the mind. If, as sometimes happened, the title "moral philosophy" seemed too narrow, it was replaced by the fuller phrase "mental and moral philosophy."

Philosophy Distinguished from the Special Sciences.—Since the middle of the 19th century it has become customary to describe physics, chemistry and biology as natural sciences rather than as branches of natural philosophy, and some parts of what was once called mental and moral philosophy have also attained independent status. Psychology, economics, comparative philology, social anthropology and the theory of political institutions are all now established as empirical sciences. We may hesitate to call them natural sciences, "nature" being still used in some contexts to make a contrast with "man"; but we no longer count them parts of philosophy, since they are now studied by specialists without regard to the other parts of the traditional field. In the 20th century even formal logic has become independent as the basic discipline of mathematics. What then is left for the philosopher? Only a study like that which Plato prescribed for his guardians, but one which is inevitably more complicated than his because of what has happened in the interval.

When we in our time say that philosophy is concerned with the relations of the sciences, we must take account of the distinction between the *a priori* and the empirical sciences and, within the latter group, of the distinctions between the physical, the biological and the psychological. None of these distinctions is wholly new, but none of them could worry the ancients as they worry us. Plato was content to say that the study of the sensible world never deserved the name of science, and even Aristotle, who was himself a good observer, had no clear conception of the inductive method by which the empirical sciences have advanced since the 17th century. There are also now difficulties of another kind that arise from the development of philosophy itself since antiquity. The demands that Plato and Aristotle hoped to satisfy seem to be natural in the sense that they arise whenever men think seriously about their situation; but it has been argued that some of them are misconceived, and that there must therefore be included within the scope of philosophy the question whether some parts of the traditional enterprise are possible. Discussion of this matter is not wholly new; it began with the skeptics of antiquity and was revived many times, notably by Hume and Kant in the 18th century. But it has become especially important in the 20th century when philosophy has been finally disentangled from the special sciences and criticism is more vehement than ever before.

No one wishes to deny that there are genuine problems about the relations of the sciences that can be solved only by hard thinking. The status of *a priori* truth in relation to empirical science—in particular, the problem of the foundation of mathematics—is obviously one such. Another that looks as though it could never be solved by empirical methods is that of the connection between mind and body. From time to time we may despair of our ability to answer these questions, because none of the suggestions that has been put forward seems satisfactory and we can think of nothing better; but to admit this is not to say that there are no such questions. Similarly, no one wishes to deny that the hard thinking required to solve philosophical problems must be dialectical in a large sense of that word; *i.e.*, not Hegelian or Marxian, but simply thinking in which we clarify concepts by exhibiting the relations between them and showing that denial of these relations would lead to absurdity. Many modern philosophers follow G. E. Moore in calling such thinking "analysis," and some use that word as a synonym for philosophy much as Plato used his word "dialectic."

There are advantages in the adoption of a new name for the philosophical method, since "dialectic" may lead to misunderstandings for the reason explained above. But "analysis" in its turn may introduce the misleading suggestion that it is the business of philosophers to find what Lord Russell once called logical atoms.

Positivist Criticism.—So far there is no radical departure from the Platonic tradition. On the other hand, there has been strong opposition in the 20th century to all talk of a distinction between appearance and reality (in any but the common-sense way in which it may be said that someone appears bad-tempered but is really quite amiable) and to all talk of justifying a religious outlook by proving something about the world as a whole (as, for example, that it was created by a benevolent God or that it will inevitably evolve toward some highly desirable consummation such

as a classless and stateless society). The writers who are most active in this opposition sometimes call themselves positivists; but unlike Auguste Comte, who invented the name, or Kant, who preceded Comte in rejection of transcendent metaphysics, they do not base their case on the supposed difficulty or impossibility of getting any knowledge about objects that cannot be investigated by the methods of the positive sciences. Their thesis is more like the contention of Hume that it makes no sense to speak of such objects, but is based on considerations about language derived in large part from Ludwig Wittgenstein.

At first the philosophers of this modern positivist school maintained that no utterance in statement form could be literally significant unless it was either (*a*) a tautology, interesting only as an expression of conventions for the use of words, or (*b*) verifiable in experience. According to one epigrammatic formulation of their view, the meaning of a statement is the method of its verification. Taken strictly, this thesis commits the holder not only to phenomenalism (*i.e.*, to the doctrine that statements about material objects are reducible to statements about the sense experiences to be expected in various conditions) but also to solipsism (*i.e.*, to denial of the existence of other minds) and even to the assertion that statements about the past are meaningless unless they can be taken as predictions of the experiences which would be said to establish their truth. Phenomenalism was once favoured by many philosophers, in particular by positivists like Ernst Mach who disliked talk of imperceptible physical objects such as atoms; but solipsism is a doctrine that no one outside a lunatic asylum can find congenial, and the reduction of statements about the past to statements about the future is plainly absurd. There have therefore been various attempts to avoid these unpleasant consequences; it was argued by some enthusiasts, for example, that the really important task for a positivist philosopher is to show the possibility of the unification of science by the formulation of all significant statements in the language of physics. Whether this thesis about the sufficiency of the language of physics is true or false (and it seems to be false), it clearly involves a large departure from primitive positivism, since modern physics is full of statements about objects that are essentially imperceptible.

When theoretical physicists constantly make successful use of hypotheses about electrons that are much further from the realm of common sense than any speculations of St. Thomas about the behaviour of angels, even those who pride themselves most on the hardness of their heads must allow that there can be no objection in principle to talk of nonsensible objects. But critics of traditional philosophy may still argue with justice that it is powerless to prove all those propositions about suprasensible objects which have been asserted by philosophers in the past; for instance, such propositions as that the world was created by a benevolent God or that souls survive the death of their bodies. For the special method of philosophy is dialectical analysis, and it is evident (or can be made so without much difficulty) that a proof of such a proposition cannot be merely the clarification of a concept.

In the past there has been some confusion about this because different kinds of inquiry have not been distinguished clearly one from another. Thus the proposition that there is a God has been taken by most people to be one that can receive empirical confirmation (*e.g.*, from events that look like answers to prayers), and philosophers who have tried to prove it have usually made some appeal to empirical evidence. But this same proposition has also been treated by some philosophers as one that cannot be weakened empirically (*e.g.*, by the *absence* of events that look like answers to prayers). The two views are incompatible, since no hypothesis can receive confirmation from experience unless it is also at least open to infirmation by experience. Another example of such confusion is to be found in the Marxist account of the evolution of society. According to its supporters, this is not only a scientific theory, well supported by historical evidence and useful for the making of predictions, but also a metaphysical principle that could never be thrown into doubt by the failure of the predictions which enthusiasts professed to have derived from it.

Since the peculiarity of such theses was first noticed it has sometimes been suggested that it is characteristic of metaphysics to present as *a priori* truths propositions which could be established, if at all, only empirically. This is an unfortunate generalization (or, on another interpretation, an unfortunate proposal for a definition), because the work of Aristotle called *Metaphysics* contains only one book to which the criticism applies. For the most part he and his followers have discussed under this title such questions as the status of universals, the existence of substances (or basic entities) and the nature of causation: in short, problems that can be solved only by dialectical analysis, since they arise from puzzlement about concepts.

Clarification and Discovery.—In an account of the task of philosophy in the 20th century it is not necessary to strike out Plato's suggestion that dialectic will lead to knowledge of the nonsensible; for even positivistic philosophy is concerned with abstractions. But it must be appreciated that this study is something quite different from the concern with nonsensible objects noted in theology or in modern physics. Whereas the theologian and the physicist both profess to give us information of which we should otherwise have no inkling, the philosopher, whose work is clarification, not discovery, can only set the familiar in a new light. As Socrates said, the answers to the questions which he asks must be known already in some fashion, though never before explicitly formulated. Admittedly, philosophers in all ages have discussed questions about the existence of God and the survival of human souls, and many have professed to give proofs or disproofs of these theses. But this is not surprising; for such inquiries are closely connected with the conceptual inquiries of the philosopher. If, for example, the immortality of the individual soul were proved empirically, we should say that the conclusion was of philosophical interest, not only because it has in the past interested some persons called philosophers, but also because the settlement of the question would involve the drawing of conceptual boundaries in a field which has so far been mapped only with dotted lines and pictures of monsters.

It may perhaps be thought curious that empirical discoveries should have any bearing on conceptual inquiries; for we have an inclination to say that all questions about meaning must be settled before any questions about fact can be raised. But this is a mistake. In ordinary language, as distinct from the language of a strictly axiomatized system such as geometry, the boundaries of the applicability of words are not drawn in advance of all applications; on the contrary, such rules as exist are established by usage, and it is often quite easy to think of circumstances for which there is as yet no rule. When the need arises, a rule is established by the adoption of some analogy which seems decisive at the time, and from then on the language is more determinate than it was before.

"Soul," which is the key word of the example, does not occur in ordinary talk, except in such phrases as "the life and soul of the party." It has, indeed, a usage in religious contexts, but this depends on assertions that have not been verified in a fashion generally acceptable to scientists or even developed imaginatively to any satisfying degree of detail. We are therefore unable to understand exactly what we are asked to believe. Sometimes it seems relatively easy to imagine situations in which we should feel constrained to say that the survival of a soul had been proved; but at other times the supposition seems senseless, because personal identity is connected so intimately with bodily continuity that no incidents of the kind described by spiritualists could ever satisfy us. Getting messages through a medium from a dead man would undoubtedly be something like getting messages through the post from an absent friend; and, if the latter is to be taken as evidence of personal survival, why, it may be asked, should not the former also? On the other hand, the survival of a friend who sends messages through the post cannot consist solely in our receipt of the letters; we must assume that he wrote the letters and dispatched them. Do we know even in outline what it means to say that the soul of a dead man has sent a message through a medium? And if not, what is the use of making the remark? The bewilderment which these reflections produce is a sign of the incompleteness of our intellectual map; but the recognition of that incompleteness is itself a philosophical achievement. In ordinary

life continuity of memory and bodily continuity are both used as criteria of personal identity. Often one is used without the other, but only because they always give the same result when they can be applied together; and so our present use of the word "person" is tied to both, though we might come to use the word differently if the normal association of phenomena were not maintained.

Philosophy and Language.—In the latest phase of the philosophical movement started by Wittgenstein there is no longer any attempt to formulate a general principle for distinguishing between sense and nonsense, not because the supporters of the movement are less critical of the utterances of older philosophers but because they have come to appreciate that language is much more complicated than they once supposed and may therefore "go wrong" in very many different ways. According to this view, ordinary language—that is, the language in which men conduct their practical affairs—is part of the way of life to which it belongs, and all philosophical troubles arise from perversion of it. Words and phrases have meaning not necessarily by standing for things, as proper names may be said to do, but by having a customary use in communication. So long as speakers observe the customs, what they say must at least make sense, though it may of course be unfortunate in various ways. If, however, speakers depart from ordinary usage and introduce novelty, there is always a danger of their talking nonsense, even though the novelty has been suggested by an analogy with something in ordinary usage. Bad philosophy is the theorizing which arises in such situations, and good philosophy consists in making clear the conventions that have been violated. When we are caught by bad philosophy, we are like flies trapped in a bottle; we buzz about continually, hurting ourselves against invisible barriers, unless we are clever and patient enough to crawl out slowly by the way by which we came in. In short, good philosophy is just liberation from bad philosophy, and its method is a therapeutic technique something like that of psychoanalysis.

It is not difficult to find examples of bad argument into which great philosophers have been led by false linguistic analogies. One about which there is no longer any serious dispute is the ontological argument for the existence of God. According to this, God must exist, because we mean by "God" a being such that nothing more perfect could be conceived, and there would therefore be a self-contradiction in saying that God does not exist. The reasoning is obviously based on the assumption that the word "exists" may be said to ascribe a perfection; that is, a character for the possession of which a thing is to be praised. But the word "exists" is not in fact used to ascribe a character to things. When we say that a so-and-so exists, we mean that something is a so-and-so; *i.e.*, we assert a proposition which is entailed by every proposition to the effect that a particular thing is a so-and-so. Before Wittgenstein wrote, this truth had already come to be generally accepted as a notable result of analysis in the philosophy of logic, and so there is here a clear case in which good and bad philosophy are related according to the account given above. It would be a serious mistake, however, to suppose that the history of philosophy is nothing but a succession of linguistic muddles. Even the debate about the ontological argument has an interest that is not explained by this description. In a society whose language did not allow for an assertion of existence by any such formula as "God exists" or "God is," the argument could never have occurred to anyone; but what made it seem plausible to Anselm and to a number of very intelligent men after him was something in their religious attitude. They used the word "God" to refer to the object on which that attitude could be appropriately directed, and it seemed to them plainly absurd to say that God's existence was contingent; *i.e.*, that there might have been no God. Now the fact that men have a disposition to take up a certain attitude furnishes no proof of the existence of anything that would be an appropriate object of that attitude; and it might be contended that our ancestors fell into a new and even more serious mistake when they passed from polytheism, with its stories of the birth of the gods, to monotheism, with its assertion of the absolute independence of God. But if there was any such mistake, it occurred long before anyone thought of the ontological argument, and there can be no satisfactory philosophy of religion which ignores this fact.

So too in other fields of philosophy, linguistic confusions when they occur are only incidental to larger problems that cannot be posed or solved without reference to the progress of the special sciences. Men do indeed misuse their language from time to time, but when such misuse has a philosophical interest it is a symptom rather than a cause of intellectual malaise. The patient who has brought himself to a metaphysical neurosis by a purely grammatical eccentricity does not exist outside the imagination of the would-be therapist. Nor is it much better to say, as some modern philosophers do, that all philosophical questions are concerned with "logical grammar." For if "logical" is to be taken in its usual sense (*i.e.*, as signifying connection with the science of logic), the statement is false; and no one has explained any other sense for the word that allows the statement to be both true and useful.

Relation of Philosophy to the Sciences.—The chief point of interest that has emerged from modern attempts to characterize philosophy is the importance of distinguishing dialectical or analytical inquiries about meaning from empirical inquiries about fact. Recognition of this should produce a becoming modesty in those who profess philosophy, but it should not make them abandon the Platonic ideal of a study that is synoptic, gives mastery of abstractions and leads to wisdom of attitude. By continuing to make the last of these traditional claims they do not commit themselves in advance to support of any religious system but simply undertake to present things in such a light that men's feelings may be reasonably grounded. The need for this is especially obvious in moral philosophy, since persons who are conceptually muddled often manifest great moral earnestness in defense of positions that are quite irrelevant to morality. But the need remains the same in all philosophical inquiries, including even discussions of the foundations of mathematics. For it is obvious to a careful observer that persons who put forward theses about the nature of mathematics are emotionally involved, and while it must be supposed that some of them are just confused, it must also be allowed that a certain attitude may perhaps be a necessary condition for the making of discoveries. Thus it can scarcely be an accident that no great mathematician has ever accepted the conventionalist view according to which mathematical truths are man-made.

It follows from the account of philosophy given here that it is impossible to summarize its results in the way appropriate to an article on any of the special sciences. The results of the philosophical work that has been done in the past are to be found in the present organization of studies. It cannot, indeed, be claimed yet that there is a single, coherent world view; but apart from the observations and hypotheses of scientists, there are some pieces of conceptual framework about which there is no serious disagreement among educated men. These are the principles used for the classification of studies in the universities and in encyclopaedias. In order to convince himself of their philosophical character the reader need only contrast, say, the *Encyclopædia Britannica* with Pliny's *Natural History* and notice that the intellectual progress of the intervening 2,000 years has involved a clarification of ideas of explanation as well as an accumulation of discoveries. If anyone claims that the clarification of ideas was incidental to the development of the special sciences, we can agree without difficulty; for the distinction made here between clarification and discovery is not supposed to be a division of labour among different faculties.

Organization of Philosophical Studies.—There must nevertheless be some division of academic labour in the modern world, since it is no longer possible for any one man to be a leader in all branches of learning. Perhaps Leibniz, who died in 1716, was the last universal scholar, and his life is a warning rather than an example. In this situation the teaching of philosophy is more difficult than ever before, but also more important. Since no one can hope to contribute much to the clarification of ideas in mathematics who is not himself a mathematician, or to the clarification of ideas in physics who is not himself a physicist, and so on throughout the table of the sciences, it seems inevitable that there should be evolved a number of philosophical disciplines corre-

sponding to the various branches of study whose concepts need investigation. We have philosophy of mathematics (or the theory of foundations), philosophy of physics (including cosmology), philosophy of history (no longer understood in the Hegelian sense as the setting out of a plan to be realized by events, but consisting in a study of historical ideas and methods), philosophy of law (or jurisprudence), philosophy of criticism (or aesthetics), philosophy of language and philosophy of religion. We may expect to hear also of philosophy of biology and philosophy of psychology. Whereas previously many scientists were frightened by talk of philosophy (and not without reason, since professional philosophers were sometimes obscurantists who opposed the growth of new studies), it seems now to be admitted that discussion of the philosophy of his subject (preferably in connection with its history) may be a useful part of the education of a future specialist.

Although some philosophical studies can be distributed among the various faculties of a university in the way suggested, there are others, including some of the most important, that cannot be associated with any specialism because the ideas with which they deal are common to all studies or not involved in any.

First there is epistemology, or the theory of knowledge and its relation to experience, to belief and to language. For Plato this was already an important philosophical inquiry, and in the 17th century it came to be regarded as the necessary preliminary to all other philosophical studies. The reasons for which epistemology obtained this primacy may have been bad; but if philosophy is the dialectical clarification of concepts, it may reasonably be expected to include some explanation of the need for such clarification, and the explanation should come early in a systematic course of study. At the beginning we need some examples of philosophical work taken from one of the special branches of philosophy mentioned above; but when we have learned to distinguish this kind of inquiry from others, we can profitably investigate the nature of the thinking that gives rise to it. This leads on naturally to a philosophical inquiry about the status of minds in the world.

Next there is metaphysics. Here belong not only the task of clarifying very general notions, such as those of substance and causality, but also attempts to throw light on the relations of the sciences (in particular of physics and psychology) by philosophical method. System building has led to so many failures in the past that it must always be regarded with caution; yet it is important that the project should never be wholly abandoned by academic persons. For if academic persons behave as though they had no interest in the intellectual questions that seem most important to other men, the gap that they leave will soon be filled by others less qualified. By the study and transmission of the history of thought academic persons can at least make it possible for men to see modern difficulties in perspective, and if the difficulties are of a sort to be solved by philosophical analysis, this is some contribution toward a solution.

Third there is ethics, or the philosophy of moral judgment. This cannot be assigned to any specialism other than philosophy itself, because moral judgment is not an activity for experts but something in which we are all authorities. In the past the teaching of ethics has often been confused with casuistry (*i.e.*, the attempt to set out a detailed moral code by the compilation of moral judgments on situations of all possible varieties) or with exhortations to virtue. Like all other branches of philosophy, ethics is in fact a theoretical study in which we try to clarify concepts. If it has more immediate practical importance than any of the others, that is because muddles about the fundamental notions of morality can have serious consequences in human action.

PHILOSOPHY, HISTORY OF. Separate histories of the numerous philosophical schools, surveys of the development of separate disciplines such as logic and ethics, accounts of the central problems such as skepticism, and, finally, studies of individual philosophers appear under appropriate headings throughout this encyclopaedia. Here we shall attempt to give a more comprehensive view of the history of Western philosophy from ancient Greece onward and to show the succession of the various schools of thought and their reaction in response to criticism from one another.

This article is composed of sections as follows:

I. Ancient Philosophy
  1. Pre-Socratic Philosophy
  2. From Socrates to Aristotle
  3. From Aristotle to the 1st Century A.D.
  4. Later Greek Philosophy
II. Patristic and Medieval Philosophy
  1. Patristic Philosophy
  2. Byzantine Philosophy
  3. Arabic Philosophy
  4. Jewish Philosophy
  5. Western Philosophy
III. Modern Philosophy
  1. Cartesianism
  2. Spinoza and Leibniz
  3. Locke and the "New Way of Ideas"
  4. Sense and Reason in the 18th Century
  5. The Enlightenment, Kant, and Hegel
  6. 19th and 20th Centuries
  7. Empiricism, Logical Analysis, and Linguistic Philosophy

I. ANCIENT PHILOSOPHY

The name "philosophy" is itself Greek, and ancient philosophy will, in the survey which follows, be understood to be limited to the philosophy of the Greeks, with its continuation during the Roman period down to the reign of Justinian I. Such a restriction sounds at first arbitrary but is perhaps justified by these considerations. The contact of the Greeks with foreign religion and ideas was only spasmodic. The mythologies of Babylonia and of Egypt, within which the germ of science was included, were not without influence upon the earliest Greek thought. Later, the Platonic Academy (4th century B.C.) showed knowledge of and interest in the dualistic religion of Persia. Some scholars think that there are traces of oriental influence in the system of Plotinus, though others again assert its wholly Greek character. Alexandria, in any case, was a centre In which Jewish and Greek ideas came together. Yet these influences are not close or continuous or certain enough to make it worth while to compare Greek and oriental philosophy in one survey, and it seems to have been always the Greek genius which converted mythology into science or philosophy as we should today understand them. The medieval thinkers, Arabic and Jewish as well as Latin, derived their view of the scope and problems and methods of philosophy from the Greeks. Chinese philosophy and Indian philosophy (*qq.v.*) must be considered quite separately.

In the development of ancient philosophy, four phases may conveniently be distinguished.

1. Those who belong to the first phase, commonly termed pre-Socratic, try to give a rational account of the origin and existing state of the world and the powers operative within it. Parmenides and the Eleatics, who directed their attention not to the physical world but to being in general, nevertheless come within this first phase; it was their historical function to show the complexity and difficulty of the concepts of change and movement; and by doing this they deflected for some time the course of physical inquiry, though they did not arrest it. The science of mathematics probably emerged during this first period.

2. A new phase opens when, in the 5th century B.C., moral and practical problems are brought to the front by Socrates and the Sophists. Socrates, however, did not urge men to desist from scientific inquiry (that is a false, though ancient, view of the part that he played) but, as will be explained, gave a new impulse to science itself. During this period, likewise under the impulse of Socrates, the question within what limits scientific knowledge is possible begins to be recognized as one of the problems of philosophy; and both logic and the theory of knowledge date from this time. Otherwise, the confident endeavour to gain the widest possible knowledge of nature, because of its intrinsic interest, goes forward. Aristotle and his immediate successors may in this way be considered the latest representatives of a movement having its centre at Athens and initiated by Socrates and the Sophists.

3. A third phase extends from the early 3rd century B.C. to the

1st century A.D. With the decline of the self-governing city-state, social conditions were transformed and at the same time the speculative spirit was beginning to grow weary. There now appeared rival systems of "philosophy," which agreed in offering such a world picture as might bring peace of mind to the individual, however little favoured by circumstances. Happiness was no longer associated with political exertion. The disinterested pursuit of knowledge was no longer recognized as essential to philosophy, and ethics (in a practical sense) became its vital part. It is true, however, that the sciences were at this time beginning to flourish independently of philosophy.

4. Finally, from the 1st century A.D. onward, there is a revival of speculative confidence, accompanied by an intelligent and respectful interest in the classics of earlier philosophy.

1. Pre-Socratic Philosophy.—In the *Theogony* of Hesiod we have a description in epic style of the formation of the world from chaos, the emergence of several generations of gods, and the successive ages of man. These, with frank pessimism, are depicted as a decline from the Golden toward the Iron Age. This is already not far from philosophy, and the borderline will be crossed when the narrative form and the reference to personal agents are abandoned, when prose is employed instead of poetry, and when a system resting on rational deduction and to some extent on observation is put forward. In the 6th century B.C. these conditions are fulfilled in men who flourished at Miletus and elsewhere on the Greek fringe of Asia Minor. These thinkers all deal with the development of a varied world out of one basic substance (not yet called by that name). This is not supposed to be lifeless, but rather endowed with some intrinsic power of development. As for the law by which development is governed, Anaximander holds that there is a "justice" in the cosmos whereby each particular substance, having exceeded its bounds for a time, must pay recompense to others. It appears also that, in accordance with this law, the cosmos will at fixed intervals be dissolved to allow chaos to resume its rights. Anaximenes, somewhat later, introduces the influential idea that it is by a process of contraction and expansion that the one substance appears as many.

The use of systematic observation by these thinkers is at best occasional, they assume no necessary sequence of cause and effect, and their thought has many archaic features. They regard the world as "divine" and do not seem to see themselves as antagonists of the traditional religion. They come to fulfill, rather than to destroy. In Xenophanes of Colophon, however, we find a hard-hitting critic of the theology handed down from Homer and Hesiod. He seems to have asserted the unity and omnipresence of God; and he is ranked by Plato and Aristotle as a precursor of Parmenides.

In such cosmogonies as those of Hesiod and Anaximander, one basic entity is supposed to grow into many and to become possessed of diverse qualities. Parmenides, by an analysis of the idea of "being" itself, arrives at the view that this change is impossible. He returns to the poetical form of exposition and gives two alternative and, in his opinion, discontinuous accounts of the world. The first is an account of reality, which, as it is based on reason alone, is true. The second is a description of appearance and takes the form of a cosmogony not unlike those which previous thinkers had offered. Only at this level are qualitative change and movement admitted. "Being" itself must be perfectly homogeneous, immune from change, and timeless; *i.e.*, beyond any distinction of past, present, and future. Being cannot have an origin, for this would have to be "not-being," which is unnameable and inconceivable. The being of Parmenides is not personified; and though a theology could be founded on his deduction, his own use of it is purely logical.

At this point some mention must be made of Heraclitus and of Pythagoras and his early followers, whose systems have always been supposed to precede Parmenides' but are only to be understood, according to the more probable view of Karl Reinhardt, as a later response to his thought. Heraclitus replies that the tension between opposites, governed by a rational principle which holds them in balance, is the key to an understanding of the world. (It seems to have been the self-styled Heracliteans of a later day who developed this into a belief in universal change, involving the consequence that all judgment is relative and science impossible. From such a conclusion Heraclitus was held back by his insistence that "measure" and "logos" [= reason] remain firm in a changing world.) As for Pythagoreanism, it seems to have been, in its first form, a system whereby the series of numbers was made to evolve from more abstract principles and the sensible world was in turn derived from number.

Whatever may be the relation between Parmenides and these two movements, the effect of his argument upon subsequent philosophy, for a long time to come, was decisive. No one was able to question this reasoning, which seemed to show the need for a persistent substance; but no one could resign himself to the belief that a moving, physical world is forever beyond the range of rational explanation. Systems therefore now arose in which, in deference to Parmenides, qualitative change was abandoned, but plurality and local movement were retained. This is the procedure of Empedocles, of Anaxagoras, and of the first atomists, Leucippus and Democritus. There are important differences between these systems. The Parmenidean attack on "not-being" involved the denial of empty space or void, and in this both Anaxagoras and Empedocles concurred, professing to be able to explain movement without such an assumption. The atomists, being persuaded that the void was really essential to the possibility of movement, sought to establish its existence both experimentally and by reasoning. Again, Anaxagoras in contrast with the atomists boldly accepted the view that matter is infinitely subdivisible, precisely as abstract extension is. Moreover, Anaxagoras and Empedocles raised two new questions and gave contrasted answers to them: how does movement first originate? and what is the cause of structures and processes which seem to be purposive in character, especially in the plant and animal world? Greek philosophy was now passing beyond the belief that the power of movement might be assumed as a datum in the original substance.

Apart from such indirect influence, Parmenides also had followers of his own, Zeno of Elea, Melissus, and the rhetorician Gorgias. Zeno of Elea is responsible for a modification of the Eleatic thesis, inasmuch as he starts not, as Parmenides did, from "being" but from "the one." For Parmenides, unity was rather the first attribute of being. Zeno shows that plurality in any form, including the abstract units demanded by the arithmetician, is monstrous and inconceivable. His famous paradoxes about movement, reported by Aristotle in the *Physics*, have a similar purpose. In Zeno and Gorgias, the dialectical technique which Parmenides had adopted with a metaphysical purpose in view has obviously become an end in itself; the latter should probably be regarded as a critic, not as a follower, of Parmenides. (*See* also articles ELEATIC SCHOOL; and IONIAN SCHOOL OF PHILOSOPHY.)

2. From Socrates to Aristotle.—There is a change of atmosphere during the second half of the 5th century B.C., and the principal scene of events during this and the following century is not Ionia or Italy but Athens.

Socrates.—There were two sides to the change of atmosphere. On the one hand, there was a general tendency to turn from natural science and speculative cosmology toward human affairs and practical problems. Socrates (*c.* 470–399 B.C.) certainly pointed out this road (*see* Plato, *Phaedrus*, 229e–230d); and in this he was assisted or preceded by the older Sophists, such as Protagoras, who made it their business to provide an intellectual training for the man of action in the democratically governed Greek states. On the other hand, there was the aspect in which Socrates alone was the innovator: it was his mission to propound basic questions hitherto overlooked, both in the sphere of physics and in that of ethics, and thereby to expose latent dogmatism and to make his contemporaries aware, for the first time, of problems concerning philosophical and scientific method; and here the Sophists were no longer the allies of Socrates but his opponents. His classic debate with them, recorded in several of Plato's earlier dialogues, turns on the questions whether moral virtue can be taught and whether there is one form of moral goodness or several; and the Sophist professes to *know* the answer to these questions, while Socrates does not. Hence the difficulty of deciding whether to

range the Sophists together with Socrates or in the earlier period.

The former aspect of Socrates' work is well enough expressed in the aphorisms which Cicero derived from his Greek teachers; namely, that he brought philosophy down from heaven to earth, introduced it into the cities and houses, and made it inquire into manners and morals. Yet if this were all, he would have been only one moralist among others, and full justice is not done to his achievement unless he is viewed as an innovator in the sphere of method, who opened up new possibilities to physical science itself and posed new problems to the philosophers. He was no despiser of physical science and did not wish to make other men desist from it as fruitless or impossible. He himself had soon abandoned it, but only in order to raise problems which were not without a bearing on its future progress. The earlier physicists had emphasized matter at the expense of form, and the Sophistic contemporaries who shared his interest in practical questions were more concerned with describing the moral qualities than with defining them. He inferred, apparently from the example of the practical arts, that the great test of knowledge is the ability to state what a thing *is*, what is the unvarying essence which a word, if rightly used, denotes. His persistence in posing this question and subjecting others to cross-examination led, in due course, to the discipline which came to be known as logic; and another offshoot of the same demand for a definition of moral ideals was the Platonic doctrine of transcendent ideas or forms (*see* FORM).

This view, whereby Socrates is an important figure within the progress of science, is stressed by Plato, in the *Phaedo*, and by Aristotle, in the *Metaphysics*, both of whom would claim to be following in the Socratic tradition. (*See* further ETHICS, HISTORY OF; LOGIC, HISTORY OF; SOCRATES; SOPHISTS. The first two of these articles are relevant also for all that follows.)

Cynics, Cyrenaics, and Megarians.—Plato was only one of several writers who commemorated Socrates, and various schools were commonly supposed to be affiliated to him. Antisthenes seems to have held up for admiration the physical sturdiness of Socrates, his self-control, and his contempt for worldly goods; he declared himself an enemy to pleasure, and he opposed the Platonic doctrine of ideas (presumably in what he thought to be the true spirit of Socrates). From him, through Diogenes of Sinope, descend the Cynics, preachers and moralists contemptuous of all conventions, who reappear in one guise or another on several occasions in the Hellenistic and Roman periods. On the other hand, the Cyrenaics, who considered that pleasure in itself is good and pain evil, were affiliated to Socrates through Aristippus; such a thesis is, in fact, maintained by Socrates in Plato's dialogue *Protagoras*. Another member of the Socratic circle founded a school which lasted for several generations; this was Euclid of Megara (*see* also MEGARIAN SCHOOL OF PHILOSOPHY). He upheld the Socratic procedure of teaching by dialogue and, like Socrates, had a moral and practical purpose. In other respects his doctrine owed something to the Eleatics. Later there was some hostility between his followers and Plato's, and the Megarian school became a nursery of dialecticians.

Plato.—Whereas the sources for all the doctrines mentioned above are fragmentary, the entire writings of Plato (428/427–348/347 B.C.) are extant and there is even, from Aristotle and Theophrastus, some indication of his unwritten teaching. Plato remains faithful to the dialogue form, and, until a late stage in his career as a writer, uses Socrates as the principal interrogator; but Socrates then subsides into a listener's role, other speakers come to the front, and Plato begins to define his position with reference to the older systems—to Parmenides, to Heraclitus, to Pythagoras, and their surviving representatives. The subjects treated are: the nature of the soul and of causation; the presence of design in the physical world; "being" and its various senses; human knowledge and the relation between thought and sense perception and language. It is convenient here to concentrate upon the first two of these. The doctrine of the *Phaedo* is that the soul is akin to the permanent and invisible, the body to the changing and perceptible. The nature of this affinity was not, at that time, further explored (the soul is never declared to be a "form"); but, together with other arguments, Socrates says that it is enough to give us confidence that the soul will survive the body. The soul is not, at this stage, regarded as a source of change but rather as a perfectly unchanging being. In the *Theaetetus*, Plato demonstrates that the senses alone can present only a series of changing impressions. They cannot even relate these to one another, still less convey knowledge of forms which have no sensible counterpart. In the *Phaedrus* and in the *Laws*, he develops a new doctrine of the soul which is also a theology (since God is a perfect soul). The soul is by its essence a self-motion, the source of every movement which bodies display. Bodies, once they have received movement from soul, can impart it to one another; but there is no movement not initiated by soul. This does not mean that the soul is in space, for the primary movement with which soul stirs itself is that of reflection or foresight, and the physical movement is secondary.

There are, however, random and irregular movements in the cosmos; and it is only soul with mind or reason (*nous*) inherent in it which can impart regular movement. The word *nous* has a complex previous history. Plato tells us repeatedly that *nous* cannot exist alone, that it must inhere in a soul (*Sophistes, Philebus*, and *Timaeus*). The doctrines of forms and reminiscence (the argument of Plato's *Meno*, that knowledge is "recollection" of truths already known by the soul) do not seem to have been abandoned by Plato at the time when he was working out this later system; and presumably a soul with *nous*, or rational soul, would be one which is guided by steady intuition of the forms. Making the best use of the science available at the time, Plato undertakes to show, or rather says it can be shown, that the principal movements in the cosmos, including that of the sun and planets, are in fact perfectly regular. Given the principles that he has just stated, it follows that the world is controlled by divine beings, perfect souls to whom we are akin. He presents this teaching (*Laws*, books x and xii) as the exact reverse of what many persons, under the influence of the Sophists, were coming to believe. In the *Timaeus* there is an account of the origin of the world in which the following factors are involved: (1) the forms; (2) the "artificer," a personal agent who is guided by intuition of the forms and from whom regular movements in the physical world, as well as all adaptation of things to a purpose, are derived; (3) the world-soul, which is formed by the artificer and serves, as it were, as his representative; (4) the "receptacle," within which qualities or powers exist in shuffling disorder, until the artificer regulates them by measure and number. This last factor is identified with space, but also has some of the functions which in Aristotle's terminology belong to "matter." In view of later developments in theology, it is to be noticed that Plato's "artificer" is not the source of all reality and is not the creator, in the full sense, of either form or matter. Another important metaphysical distinction made in the later dialogues is that between "limit" and "the unlimited," two factors which combine to form a "mixture"; the mixture must have a "cause" and, where this cause is "reason," will be harmonious and durable. Here there is an even closer approach to the Aristotelian distinction of form and matter (*Philebus*, 23–26).

Aristotle.—According to Aristotle (384–322 B.C.) there are four factors in every process of causation, whether natural or artificial: form and matter, which never exist apart from one another, being correlative; the motive cause, from which the change immediately proceeds; and the end "for the sake of which" the process occurs. This analysis is meant to be applied not only to physical change but also to such processes as teaching a science or imparting moral discipline to a child. The "matter" upon which form is imposed will in that case be the untrained capacities or emotions, and it is plain from this that the Aristotelian "matter" is quite different from what is so termed in modern physics. Another point to be noticed is that Aristotle is here distinguishing factors in causation rather than causes in the modern sense and that his "causes" may be contemporary with, or even subsequent to, the processes caused; *e.g.*, if a man walks for the sake of health, health is a "final cause."

Aristotle applied his analysis to the criticism of his predecessors, including Plato. For a long time, matter had been the only one of the causes to be recognized; subsequent thinkers had had a glimpse of the efficient and formal causes, but no one had yet suc-

ceeded in naming all four. No addition to the analysis was conceivable, and in this respect it was the completion of all previous thought, the goal to which others had struggled without clearly perceiving it. Plato is complimented by Aristotle for his clear recognition of the formal cause (and here Aristotle shows the genesis of his doctrine from Socrates and the Pythagoreans); moreover, in his physical doctrine and in his unwritten teaching, he recognizes the need for a material or nonformal factor; but he has failed to give any consistent account of efficient causation (Plato's derivation of movement from the soul is, apparently, viewed in this criticism not as a part of his regular doctrine, but as a tentative suggestion).

Aristotle's positive views grow naturally out of this criticism. By "movement" is meant a transition from a "potential" state to one of "actuality," and such transition will take place only under the influence of a subject which is itself actual and can bring out the potentiality in another ("movement" here has a wider sense than in modern usage and applies to all qualitative change, whether physical or not). Once the thing has reached maturity (a state for which Aristotle coins the term "entelechy"), it will from time to time, but not continuously, display its powers in action. This display of powers ("activity," or "energy") is not exactly "movement" in the sense above defined, for it is not the realization of something incomplete. An illustration may be drawn from the acquisition and use of scientific knowledge: a boy's power of learning is developed under the influence of a teacher, this transition corresponding to "movement"; but once he has acquired the scientific knowledge, it will be latent in him whenever it is not in actual use. Hence a new contrast between possession and use is, as it were, superimposed on that between the potential and the actual. We ourselves and the beings who surround us are complex and have to inhibit one activity in order to engage in another. Growth and change in the physical world are to be explained in analogous fashion.

This conceptual analysis is then applied by Aristotle in the following way. God alone is fully actual—a form without matter, who does not have to be raised from the potential to the actual state. His activity is the uncaused cause of all change; but he is its "final cause" or goal and he does not, as in the Platonic system, design the world. The efficient cause of change is "nature"; *i.e.*, an inherent impulse in things, both living and lifeless, leading them to develop their capacities and to make use of them when developed. The Platonic definition of soul as a self-moving agency is rejected on the ground that soul cannot participate, even incidentally, in movement; and instead, soul is regarded as the "form" proper to an organic body. Such a definition does not apply to God, who is incorporeal (and, perhaps, not to the human soul *qua* rational). God is therefore viewed not as a soul but as a mind engaged in unbroken reflective activity; and Plato's axiom that "mind" must always inhere in "soul" is also silently discarded.

This survey, concentrating on the theory of causation, will perhaps have shown why Aristotle is the parent of biological science and Plato rather of mathematical physics. (For other aspects of their thought, *see* the articles ARISTOTLE; ETHICS, HISTORY OF; LOGIC, HISTORY OF; PLATO.)

3. From Aristotle to the 1st Century A.D.—The years from approximately 310 B.C. to the 1st century A.D. form another distinct epoch. Philosophy was now regarded primarily as a way of life. Scientific knowledge was no longer pursued with enthusiasm by the philosopher as such; he valued it only insofar as it made clear the position of man in the world. This was an era of increasing specialization in scientific, historical, and philological studies. Because of the changed circumstances, the philosophical idea of the good life was no longer bound up with the city-state. Slavery persisted, but the division between Greek and barbarian began to break down, and men recognized one another as brothers, with one God for their parent, whether this view was developed by the Stoics or, as Sir W. W. Tarn maintained, by Alexander the Great himself.

Epicureans, Stoics, and Skeptics.—After the first generation, the schools of Plato and Aristotle themselves began to succumb to these dominant influences (*see* ACADEMY, GREEK; and PERIPATETICS). Among newer systems, that of Epicurus (341–270 B.C.) may be considered first. Epicurus held that the physical world came into being from the spontaneous downward movement of atoms in an infinite void and that nothing further is needed to explain its existing state. It is, however, destined to be destroyed; *i.e.*, not annihilated, but dissolved into its component atoms, which will then enter into fresh combinations. Similar worlds doubtless exist elsewhere and have existed in the past. The soul is material and is enclosed in the body, from which it will escape and be dispersed at death. The gods live at peace in the spaces between the worlds, which they did not organize and for which they assume no responsibility. For the demonstration of these truths physical science is essential; beyond this it becomes superfluous. The one criterion of truth, which cannot possibly be disputed, is sense perception. The wise man will live in prudent enjoyment of physical pleasures, free from all anxiety about the future life, unconcerned with fame and other dubious goods. He will, however, for this very purpose need to acquire justice and the other commonly recognized virtues. Epicurus showed, as no one before him had done, the happiness of an inner life which is available to all; and no doubt this was why he was hailed by his followers as a "saviour." But his theory of knowledge is weak (the "ultimates" in his system, the atoms and the void, lie beyond perception, which he says is the criterion of truth), and he frankly discouraged all innovation which would disturb the basis of the system.

Stoicism on the other hand was a more flexible system which could and did develop in response to circumstances or to effective criticism from without. For a general view of this system, *see* STOICS. The doctrine was first laid down by Zeno of Citium (*c.* 320–*c.* 250 B.C.) and reestablished with far greater precision by Chrysippus (*c.* 280–206 B.C.). The Stoic ethical system at this time was strange and uncompromising, oriental rather than Hellenic in character. In the 2nd century B.C. appeared Panaetius of Rhodes (born *c.* 180), who reinterpreted the psychology and ethics of the Stoa in such a way as to stress its close affinity with Platonism and the common descent of both doctrines from Socrates. Soon after this, Poseidonius (*c.* 135–*c.* 50 B.C.) gave a new form to the physical and theological doctrine inherited from the older Stoics. As a result of the work of these powerful thinkers, Stoicism secured a new lease on life and awakened great and enduring interest in Roman circles. But throughout the last two centuries B.C. the Stoics, as the most prominent dogmatic school, came under fire from skeptics of more than one variety. The skepticism of Pyrrho of Elis, though founded on epistemological arguments which he collected from earlier writers, was really a moral doctrine; he made "indifference" in face of all external circumstances into a cardinal principle of ethics (*see* SKEPTICISM). The skepticism of the Middle or New Academy, associated mainly with the name of Carneades, was of a more intellectual character and arose rather within the main Greek philosophical tradition.

Controversies of the Schools.—The history of the years from 200 to *c.* 50 B.C. is roughly, therefore, as follows. Epicureanism, always attractive, but not participating in any development, stood in the background. The leading dogmatic system (and the only one which, in the sphere of morals, could put forward ideas acceptable either to the Roman rulers or to their subjects) was Stoicism. And while the Stoics had appropriated the moral teaching of Plato (and probably some part of the system of Aristotle), the Academy, which had surrendered those doctrines, had become the focus of skepticism. In the 1st century B.C. there was, however, the attempt of Antiochus of Ascalon to revive the atmosphere of the "Old Academy" and to pretend that Zeno, in spite of the appearance of novelty which his terminology creates, contributed nothing new to the Platonic doctrine. The debates arising from this situation are reflected in the philosophical writings of Cicero (106–43 B.C.). Historians sometimes write of a specific phase of Eclecticism, which pieces together a system from previous systems. But if there ever was such a movement, Cicero at least ought not to be assigned to it. He is a consistent representative of the New Academy, wielding a method, but hostile to the very idea of system.

When Zeno and Epicurus first established their systems, they seem to have been less conscious of opposition toward one another

than of the need for joining forces in the attack on the two reigning schools, the Academy and the Peripatos. Aristotle, being judged mainly from his dialogues, was still ranked as an idealist; Zeno and Epicurus had in common a thoroughgoing materialism. The Platonic theory of knowledge, in which the mystical belief in reminiscence always played a part, was disparaging to the senses, whereas the new schools refused to accept any foundation except the unshakable certainty of perception. Both Platonists and Aristotelians held that a wide culture in the sciences was necessary to the philosopher; Zeno and Epicurus made physics subordinate to ethics and gave it a form which even the late learner (who to Plato and Theophrastus is a comic figure) could grasp. The Platonists maintained, and both the Stoics and the Epicureans denied, the eternity of the physical world. Even in ethical doctrine the two latter schools were linked by the wish to offer some means of attaining independence of mind. When, however, their joint attack had been crowned with success, the equally important contrasts between them could not for long be disguised: one was a system of duty, the other one of Hedonism. The Stoics were believers in divine providence and regarded the world as a single divine being permeated by *logos* (reason), which attains to self-consciousness in man. In the Epicurean "theology," the gods are not allowed to design the worlds but are placed in the interspaces where they cannot do harm or have harm done to them. Thus after an interval Panaetius was able to bring round the Stoic school into alliance with the Academy in the manner above described.

4. Later Greek Philosophy.—Stoicism itself after the 1st century A.D. has little history as an organized school, though it produced writers whose names are still famous, such as Epictetus and Marcus Aurelius Antoninus. It had, however, far-reaching influence as a fertilizer in many different fields. The Stoic ethics remained prevalent, both among philosophers and among the public, as the best that pagan antiquity had to offer; the important conception of a law of nature, which all men as rational beings ought to recognize in their dealings with one another, rests on a Stoic foundation. From the Stoic armoury, Christian theologians were able to borrow many arguments concerning design in the physical world. As a coherent system, Stoicism did not survive. Not only had its dogmatic pretensions been fatally injured by criticism from the Academy; but also, from the Augustan Age onward, men sought more and more a religious view of the world such as no materialistic creed could provide.

Those thinkers who did not lapse into skepticism, which was revived by Aenesidemus, turned naturally toward some version of Platonism or to Neopythagoreanism, which is by this time not easy to distinguish from contemporary Platonism. The works of Plato were edited in the 1st century A.D. by Thrasyllus, and the treatises of Aristotle, after centuries of obscurity, had been brought to light and edited in the previous century by Andronicus of Rhodes. These are the editions from which modern texts descend. Both Plato and Aristotle were now classics in the philosophical schools and became the subject of learned expositions still preserved, in which much valuable information is embedded.

Middle Platonism and Neoplatonism.—The revival of interest in Plato took various forms. As has been mentioned above, Antiochus (1st century B.C.) went back to the ethical doctrine of the early Academy and cast doubt on the originality of the Stoics. Far more thinkers were inspired by the cosmology of Plato and by his theory of the soul, and the first development of this tendency was the so-called Middle Platonism: for example, a treatise by Albinus, of uncertain date, consists of a systematic exposition of Platonism, free use of Aristotelian terminology being made in it; in Philo is found another such exposition, this time from the point of view of a Jew of Alexandria; and in Plutarch of Chaeronea interest in the religion of Plato is especially prominent. Plutarch's attack in some of his treatises upon Stoic and Epicurean doctrines, from a Platonic point of view, seems to show that these still had some vitality.

The Neoplatonic system of Plotinus (A.D. 205–270) resembles Middle Platonism in its general intention but is much bolder and rests on a broader historical basis. He and his followers were profound students of Aristotle as well as of Plato and were deeply interested in the pre-Socratic philosophy. Giving a relatively unimportant place to the doctrine of forms, Plotinus develops Plato's doctrine that soul is the motive principle from which bodies (if they can be said to exist at all) derive their power of action; and by this means he corrects the materialism of the Stoics and others influenced by them. He proceeds to draw, much more firmly than Plato, the general picture of a graduated immaterial world. For the soul, though it is the principle of physical change, occupies only a middle position in the entire scale of reality. Above particular human souls is the world-soul, above this again the mind (Plato's "artificer") which fabricates the world-soul and in which the highest knowledge is located. Beyond mind, knowledge, and existence lies the One, which no human language can suffice to describe. The heavenly bodies are divine beings (and in defense of this view the Neoplatonists make use of arguments dating back to Plato and Aristotle); the part of the visible world in which we live is admittedly imperfect by absolute standards, but has its proper place in the graduated scale and ought not to be regarded as the work of a malicious spirit working against the Good. Astrology is condemned, as presupposing a false view of the mode of action of the celestial deities.

Plotinus entered into no controversies resulting from his work, but Porphyry (234–*c.* 305) took the offensive in a criticism of Christian doctrine, and the Athenian Neoplatonists Proclus (410–485) and Simplicius (6th century) assembled all the resources of Greek philosophy in the attempt to present a religious view that could be set up in rivalry to Christianity. Christian thinkers naturally protested against the belief in the divinity of the stars and in the eternity of the physical world and against the associated belief in precisely similar cycles of human history. On their side, the Neoplatonists thought it impiety to deny the divinity and intelligence of the stars, regarded the Incarnation as unthinkable, and held fast to their arguments which seemed to show the eternity of the world. (*See* NEOPLATONISM.)

From the point of view of a later age, this controversy seems to tend toward an issue of which none of the disputing groups was at the time aware. The created world of the theologians is a possible object of science (and, indeed, as proceeding from the inscrutable will of God, of humble experimental science), whereas the besouled cosmos of the Neoplatonists, to which man feels himself akin, is not such an object. This is a defect which neither the genius of Plotinus nor the learning of his various successors could outweigh, though it did not become obvious for many centuries. Although Greek philosophy failed in its last contest, it had provided many of the arms by which it was defeated.

(D. J. A.)

II. PATRISTIC AND MEDIEVAL PHILOSOPHY

Early Christian thinkers could not be indifferent to philosophical doctrines aiming at human happiness and dealing with the questions which religion also was intended to answer. For similar reasons some Jews, for example Philo, had interpreted Scripture in terms of philosophy and vice versa. Philosophy (particularly Platonism and Stoicism), when it was not rejected as impious, was in turn accepted as supporting revelation and used for apologetics, being considered as foreshadowing, or sharing in, Christian doctrines, or as likely to add something, in certain fields, to the incompletely revealed truth, or again as ready to be combined, in a semimythological form, with elements derived from religious texts and traditions. In the first five centuries A.D. there were no Christian philosophers in a strict sense, but the influence of Greek and Roman philosophy was widespread and deep; some doctrines were developed with originality, and the new problems of the relation between reason and faith, of the possibility of rationalizing dogmas, and of fitting new historical facts or interpretations and psychological experiences into the usual categories of thought were faced in ways which were important for the future.

Philosophical speculation from the 6th century to the 16th was mainly concerned with the issues already debated, in Greek and in Latin, by pagan and Christian thinkers, and was based on their doctrines. Interest spread to new provinces, east, west, and north. Philosophical language was created on the Greek pattern in Ar-

menian, in Georgian, and in Persian, in Syriac, in Arabic, and in Hebrew; it developed enormously in Latin and, mainly from Latin, was inserted into the European vernaculars, French, Spanish, Catalan, Italian, English, German, and Irish; it thus became part and parcel of modern speech, both technical and ordinary.

The continued interest in philosophical studies was ensured above all by the late Greek schools of Constantinople, Athens, Alexandria, etc. Foreign students transplanted in their countries some of the Greek doctrines and methods from the 5th century onward; thus the Armenian, Georgian, and Syriac schools came to life, and Latin thought was being enriched until early in the 6th century. Refugees from Athens in the 6th century and from Alexandria in the 7th carried the philosophical tradition into Persia and strengthened the Syriac schools. From these and through new contacts with Constantinople, there arose in the 9th century the cosmopolitan philosophical tradition in Arabic; and later this tradition appears in Hebrew. The Greek inheritance passed again (and much more extensively) into Latin in the 12th–15th centuries, both from Constantinople and from the Arabic west. On the other hand, Latin philosophy influenced the Greek, Hebrew, and Armenian cultures in the 14th and 15th centuries. The works which contributed most to speculation were Aristotle's treatises on logic, psychology, metaphysics, physics, ethics, and politics, several Peripatetic and Neoplatonic commentaries on the same texts, and a few independent Neoplatonic works, principally Proclus' *Elements of Theology*. Plato was directly known almost only through his cosmology (*Timaeus*) and, among the Arabs, through the *Republic* and the *Laws*. The logical principles of philosophical method, the dualities of matter and form, substance and accidents, potency and act, the four causes, the notions and classifications of virtues, the idea of man as a "political animal," and the doctrine of experience as the basis of knowledge were taken over from Aristotle and became instruments of thought through these ten centuries. Among the permanent Neoplatonic contributions to medieval speculation were the doctrines of a hierarchical organization of the world, subject to the law of efficient causality and to the one First Cause; of spiritual beings ("Intellects," etc.) as intermediaries between man and God; and of the tendency of everything to return to its origin.

The purely philosophical tradition was often supplemented, sometimes almost superseded, in those ten centuries by the philosophico-theological tradition of the Fathers of the Church and of some heretics; Christian, Muslim, and Jewish philosophers had to face all or some of the problems which they had faced. The Fathers provided, directly or indirectly, inspiration, materials for discussion, and solutions. They also added to the purely philosophical legacy by passing on Platonic and Stoic doctrines and original theories of their own. Above all, St. Augustine was ever present as an authority and a model for those who read Latin; and Pseudo-Dionysius (*see* DIONYSIUS the Areopagite) powerfully affected philosophy and theology among Greeks and Latins, Armenians and Syrians.

Starting from these premisses and often accepting the older doctrines, medieval philosophers (especially those of the Latin and Arabic tradition, to a smaller extent those of the Byzantine and Jewish) pushed further and deeper the study of the workings of the mind; attempted new or more convincing answers to old questions (*e.g.*, those of the existence of God and of the immortality of the soul); examined with refined techniques the claims of *a priori* and *a posteriori* knowledge; considerably advanced the inquiry into the functions and pitfalls of language; debated and clarified the concepts of knowledge, certainty, belief, faith and probability; tried to organize all human knowledge systematically; often asserted the supreme value of intelligence in a humanistic sense; reasserted the importance of sense experience and induction; enlarged and made more concrete the scope of social and political philosophy; and opened the way to the mathematical interpretation of physical phenomena.

1. Patristic Philosophy.—St. Paul's words "the invisible things of God from the creation of the world are clearly seen, being understood by the things that are made" (Rom. 1:20) suggested to Christian thinkers how to combine philosophy and religion; and the obviously philosophical account of the *Logos* (Word) at the beginning of St. John's Gospel would give a doctrinal basis to such a combination. The apologists of the 2nd century took a definite stand with regard to philosophy: Justin Martyr and Athenagoras confirmed Christian doctrines by showing that they agreed either with Plato's or with the Stoics' views and borrowed Philo's idea that the Greek philosophers derived their best opinions from Moses; Tatian, on the contrary, claimed that philosophy is misleading and God unknowable to human reason. At the same time, new half-philosophical doctrines were propounded which took into account the basic worry to which religion was to be a remedy: the problem of evil. The best among the Gnostics, Valentinus and Marcion (*see* also GNOSTICISM), opposed the view of evil as a positive being to the optimism of most Greek philosophy. The history of the world is one long or ever-renewed strife between Good and Evil; Evil will disappear with the destruction, not with our perfect knowledge, of this world (*see* also MANICHAEISM). In Clement of Alexandria (*c.* 150–*c.* 215) philosophy appears partly as the best instrument for molding Christian theology, partly as a forerunner of revelation; this view was to reappear in Abelard nine centuries later. Origen (*c.* 185–*c.* 254) answered Celsus' objections to Christian doctrines with philosophical arguments: the Christian God is still the "eternal immutable activity" of the philosophers, because before creating our world he may have created others and because the Incarnation meant a change in the mind of men, not in the nature of God.

St. Augustine (354–430) transformed some aspects of Platonism and Stoicism, the two doctrines which most inspired him after he abandoned Manichaeism. According to him knowledge is, above all, the result of illumination coming from God and manifesting itself within and through our own mind, whether it is concerned with dispelling the ultimate doubts about our existence or with the highest notions. Matter was not created as a barren receptacle of forms, but enlivened by *rationes seminales*, principles of development. Thence forms will supervene, each as a mark or imitation of the "exemplar" which is in the perfection of God's nature; each thing may have many forms, but every created thing, however spiritual (souls, angels), will have its own matter; this distinguishes creatures from Creator. The idea of mankind's forming the *civitas terrena* in its passing on earth looked backward to the cosmopolitanism of the Stoics and forward to the *humana civilitas* of Dante and to the more modern doctrines of a universal polity.

Pseudo-Dionysius (late 5th century) interpreted much of the Neoplatonic metaphysics of Proclus in terms of Christian theology. His analysis of the "names of God" suggested discussions on the philosophy of language, not only of theology; his *Caelestis Hierarchia* and *Ecclesiastica Hierarchia* gave the blessing of a supposed friend of St. Paul's to that theory of the degrees of being which, also from a work of Proclus summarized in the *De Causis*, implanted itself in most philosophical systems of the 13th century; while his negative theology often set the rules for the doctrines on the limits between rational and revealed knowledge.

2. Byzantine Philosophy.—After the closing of the Athenian schools (529), philosophical activities continued for more than a century in Alexandria and other centres; the Theodosian university of Constantinople probably kept them alive through the 6th, 7th, and 8th centuries, while St. Maximus interpreted and expanded Pseudo-Dionysius' doctrines and St. John of Damascus presented philosophy as a discipline introductory to theology. Photius and Michael Psellus, respectively in the 9th and in the 11th century, upheld the primacy of rational inquiry over mythological fiction and over mysteries and magic, the former supporting Aristotelianism and positive research, the latter preferring Platonism and intellectual intuition. The revival of Aristotelian studies in the 11th and following centuries (John the Italian, Michael of Ephesus, Eustratius, Theodore Metochites) spread from Constantinople into the Latin West. In the 15th century the philosophical optimism of the Platonist Gemistus Pletho, according to which all men may agree on the same "philosophical religion," and the view of Cardinal Bessarion on the fundamental agreement between Platonism and Aristotelianism directly influenced philosophers in

Italy. To Italy was transferred, after the fall of Constantinople (1453), what remained of the Byzantine philosophical tradition.

3. Arabic Philosophy.—After the early Mu'tazilites (8th century), who confined themselves to philosophical apologetic of Islam, mainly discussing the unicity of God, free will, evil, and creation, a more definite philosophical tradition in the Arabic language arose in Baghdad and spread to Persia and to Spain. The attempts of al-Kindi, an Arab, in the 9th century to combine with Islam Aristotelian and Neoplatonic theories, particularly concerning the noneternity of the world, the independence of the soul, and prophetic knowledge, were succeeded by more constructive thinking. The Persian Rhazes (*i.e.*, Razi; d. 923 or 932), a rationalist for whom science and philosophy stand higher than religion and a man of great medical doctrine and experience, expounded a system based on five eternal principles: the Creator, the soul of the world, matter, time, and space. Al-Farabi (*c.* 870–950), a Turk, again asserted the superiority of philosophy as the highest of human achievements, accessible to all men and the best instrument for establishing a sound political organization.

Avicenna (980–1037), another Persian, a more systematic and universal thinker (his *Shifa* is the first great philosophical encyclopaedia, mainly organized on the model of the traditional order of Aristotle's works), examined and elaborated most problems discussed and solutions given by authors known to him. Religion and philosophy have, according to him, an equal status, or religion is superior; this attitude is reflected in his doctrine of prophecy (*i.e.*, that it is one of the highest intellectual faculties) and in his interpretations of Aristotle's theory of the soul and of active and passive intellect. A strong reaction against philosophy came from al-Ghazzali (1058–1111), who "demolished" it by exposing its inner contradictions and established the primacy of sacred texts and rationalized dogmas. But he was soon powerfully contradicted by the greatest Spanish Arab, Averroës (1126–98) of Córdoba.

According to Averroës, philosophy alone leads to complete, pure, final truth, while sacred texts contain at best a simplified and childish account for less-gifted people, and rational theology is muddled, pretentious and misleading (the theory of "double truth" which often goes under his name was completely alien to his doctrine). His penetrating, extensive analysis of Aristotle's works was a model and a mine of ideas and information for philosophers of the Latin tradition from the 13th century onward. His commentaries and his views on philosophical truth led, probably more than anything else, to the establishment of a "free" philosophy in the west; while Avicenna's systematic order and his psychological and gnosiological analyses were of continuous inspiration in the 13th century, particularly to Duns Scotus. (*See* Arabic Philosophy.)

4. Jewish Philosophy.—If we except the syncretism of Philo and the philosophical elements in the Cabala, Jewish philosophy is closely connected with the Arabic tradition and often, indeed, written in Arabic. Jewish attempts at adapting Platonism and Aristotelianism so as to avoid contradictions with the Bible anticipated and sometimes influenced the views of Christian thinkers. Saadia ben Joseph in the first half of the 10th century proved against Aristotle that the world has a beginning and that the soul is a substance; against the Platonists, that every soul is created for its body; against the Neoplatonists, that the world resulted from creation, not from emanation. The doctrines of the plurality of forms and of the presence of matter in spiritual creatures were expounded by the 11th-century Ibn Gabirol (Avencebrol) in more definite and clearer terms than by St. Augustine and thus were taken up by the most representative Latin thinkers of the 13th century. Judah ben Samuel Halevi (*c.* 1085–1141), the Jewish equivalent to al-Ghazzali, opposed philosophy; but Maimonides (1135–1204), a man from Córdoba as was Averroës, maintained that theology and philosophy necessarily agree in spite of their different methods (this view was later held by St. Thomas Aquinas, who knew Maimonides' work). His theory that immortality consists in participation in knowledge (*i.e.*, in the eternal "active intellect") is comparable with that of Spinoza, one of his later admirers. Hillel ben Samuel, Gersonides, Hasdai Crescas, and others in the 13th and 14th centuries did not produce any important or independent doctrine. The only prominent thinker of the 14th–15th centuries, Judah ben Isaac (Leo Hebraeus), already belongs to the Platonism of the Italian Renaissance. (*See* Jewish Philosophy.)

5. Western Philosophy.—Boëthius (*c.* 480–524) did not carry out his plan of harmonizing Plato and Aristotle; but his translations and unoriginal elaborations of Aristotelian, late Peripatetic, Stoic, and Porphyrian logic provided the basis for much of the philosophical revival of the 9th and following centuries and for most logical studies until recent time. His application of philosophical methods and categories to theological problems was followed and carried further in the 12th and 13th centuries. His exaltation of philosophy as the greatest of human possessions was influential in less professional philosophical circles. Three centuries later an Irishman, Johannes Scotus Erigena (*c.* 810–877), favoured by the Frankish kings' cultural policy and influenced by Greek and Latin Fathers, especially by Pseudo-Dionysius, produced the first great synthesis of the Latin Middle Ages, the almost pantheistic *De Divisione naturae*. This, however, was to be less important than the frequent theological debates on substance and accidents and the scholastic training on Porphyry's *Isagoge* and on Aristotle's *Categories* and *De Interpretatione*. On the basis of these texts much thought was given to the relations between words and things and to the different functions of words. In particular, the question whether universal words ("man," "animal," "white," "humanity," etc.) correspond or not to definite things provided the opportunity for shaping and expounding various metaphysical and epistemological views; for example, the "nominalism" of Roscelin (*c.* 1050–*c.* 1125), the "realism" of Anselm (1033–1109), etc. On the other hand, logic was often but an instrument of apologetics; even Anselm's famous proof that God exists because we have in our mind an idea of Him harnesses some rules of logical consistency in order to make explicit a religious intuition. (*See* also Ontology.)

In the 12th century dialectic is still in the forefront. For Peter Abelard (1079–1142) philosophy meant the dialectical elaboration of religious and moral problems, supported by views from ancient philosophers. His interest was often more genuinely philosophical: systematic doubt and inquiry into the meanings of words and into the propriety of their usage were his rules in the *Sic et non;* and the true value of words, their functions in clauses, and the psychological processes connecting things and words were the subject matter of the best sections in his commentaries. At this time, the preeminence of philosophy of language is also manifest in the study of sophisms (a new and henceforward permanent feature of philosophical studies) and in other new chapters of logic (*suppositiones, relationes*, etc.). A more metaphysical interest was shown by Gilbert de La Porrée (*c.* 1075–1154), who thought it possible to separate universals, such as "humanity" or "divinity," from particulars, such as "men" or "God"; while cosmological doctrines, partly inspired by Plato's *Timaeus*, were prominent in the school of Chartres.

The bulk of the Greek and Arabic legacy was then discovered. Scholars of the Western world collected and translated books of science, philosophy, theology: Aristotle's physical, psychological, ethical, and metaphysical treatises, something of Plato, texts from Proclus, some sections of Avicenna's encyclopaedia, something of al-Kindi and of al-Farabi, Ibn Gabirol, Euclid, Ptolemy, Archimedes, Galen and Hippocrates, John Chrysostom and John of Damascus.

Some logical works of Aristotle in Boëthius' translation were also rediscovered. The first signs of the assimilation of some of these works are found in Spain (with Dominicus Gundisalvi or Gundissalinus) and possibly in the pantheistic doctrine of Amalric of Bena and in the materialistic monism of David of Dinant.

Complete assimilation was the work of the 13th century. The Church's cautious attitude toward unknown doctrines slightly delayed it; but in Oxford and soon in Paris (where a few works were excluded from the schools for some time) the process of analyzing and commenting on many of these writings led to the newly discovered doctrines being used in debates and for new constructions. Averroës became available in Latin in the 1230s, and other Aris-

totelian works, including the *Politics*, followed. Doctrines already popular in Latin had to be revised and refined. The theory of light as an element in the world and a means of knowledge was Augustinian in origin but was advanced by Robert Grosseteste (*c.* 1168–1253) in a new, more scientific spirit. Franciscan philosophers, such as St. Bonaventura (1221–74), would still accept the theories of the multiplicity of forms, of exemplarism, of matter in spiritual creatures, of knowledge by illumination, of *rationes seminales*, but they tempered them under the impact of the new texts; they faced the new doctrines or tried to find in them some support for their views. Philosophy asserted itself as something valuable in its own right; according to Roger Bacon (*c.* 1220–*c.* 1292) it can be a means of domination and well-being for mankind. The new urge to discover truth, either in the writings of philosophers, or by deduction, experience, and experiment, led to the encyclopaedic works of Albertus Magnus (*c.* 1200–80) and Bacon.

Competition between theology and philosophy, between faith and reason, became a burning issue. Although criticism was alert on all sides and Aristotle was more often than not simply *an* authority and hardly ever *the* authority, nevertheless some views that were either his or ascribed to him, as well as certain views of other "pagans" (Proclus, Avicenna, Averroës), were such as might carry too much conviction and endanger more "orthodox" doctrines (*e.g.*, the doctrine of creation or that of individual immortality). Enthusiasts and reasoning thinkers (such as Albertus) would alike proceed with their philosophical inquiries, fearless of possible conflicts, but add from time to time the rider that "this is what philosophers teach," implying or stating that in case of disagreement they themselves would be on the side of orthodoxy. Thus philosophy would be pursued for its own sake, and its value as a giver of truth would be impaired only slightly. This was notably the case with the "Averroists" like Siger of Brabant (13th century), who would adhere as much as possible to Aristotle and try to develop a more coherent Aristotelian system than Aristotle had ever produced. They avoided speaking of double truth, but came near to it; their ideal was a satisfactory account of reality independent of theological interferences.

An attempt at producing a comprehensive philosophical doctrine based on the conviction that faith and reason—philosophy on the one hand and Scripture and Fathers of the church on the other—are in agreement was made by St. Thomas Aquinas (1225–74): a magnificent compromise between orthodoxy and Aristotelian philosophy. Some provinces of knowledge are the preserve of faith; but sense experience, aided by the "first principles" (which are present in the "active intellect" of every man) and by logic, reveals the structure of the universe and allows men to approach the less accessible realities, including the existence of God. Thomas took Aristotle as his model for most basic doctrines (matter and form, efficient and final causes, categories of being, movements, and elements) but often "adapted" him and sometimes abandoned him. Thus the matter of each thing, not form, bears the marks of individuality; the highest level of reality (being) characteristic of each thing is its *one* form ("rationality" in man supersedes "animality" and other forms, it is not added to them); human soul is the form of the body, but, being individually created, is separable from it; the world is created, although "created *ab aeterno*." The Aristotelian theory of knowledge is systematized, the emphasis being put on sense experience. In this lies the philosophical importance of Thomas' criticism of the *a priori* (ontological) proof of the existence of God and its replacement by the hardly original "five ways": all of these start from sense experience. It is mainly due to Thomas that Aristotle's *Politics* and the naturalistic view of man as a political animal became the starting point of all future social and political philosophy, to which he also contributed his doctrine of the fundamental agreement between individual and common good and his elaboration of the idea of natural law.

Duns Scotus (*c.* 1265–1308) extended, in a sense, the province of philosophy. His theory of the "univocity of being," contrasted with Thomas Aquinas' "analogy of being," allowed him to apply to God, significantly and positively, our categories of thought as expressed by means of the verb "to be." His Neoplatonic vision of a perfectly organized world in which various degrees of causality keep things closely knit together is coupled with an extreme doctrine of individuality: perfect knowledge is knowledge of individuals (but again, universals are somehow existent in things). On the other hand, our rational knowledge is limited—it even seems to be made insecure—by the absolute freedom of God, who might even change the order of the world. Duns's individualism and doctrine of God cooperated with Thomas' emphasis on experience to prepare the ground for the more extreme doctrines of the 14th century.

The 14th century was a period of constructive criticism; the process of assimilation was over, and philosophy had its own independent life. Absolute determinism or indeterminism, probabilism, empiricism and rationalism, and extreme Averroism were being propounded, defended, and faced. According to Petrus Aureoli (d. 1322) knowledge is appearance of objects: we know what exists by direct impressions, more or less clearly, but without intermediaries; forms, essences, and universals are fictions. For Nicolas of Autrecourt knowledge is a bundle of appearances giving probability, never certainty. According to William Ockham (*c.* 1280–1349) we know only individuals, and only through our senses: the structure of the world, relations, classes, space and time are constructions of our mind. The order of our world of knowledge is the logic of our construction. Analyzing our language, we discover all that has been ascribed to the extramental world; only individual things resist this analysis. God's existence cannot be proved; even the "five ways" lead us beyond experience, away from the truth. Knowledge of God belongs to faith, according to which God is absolutely free; "laws of nature" or knowledge of immutable facts and entities would impair God's freedom. The fideistic side of these doctrines recommended them also to less extreme thinkers such as Jean de Gerson and Pierre d'Ailly. The opposition to what was termed "nominalism" or "Ockhamism" failed to produce positive constructions; such "realists" as Walter Burley were not very original. Even the extreme deterministic doctrine of Thomas Bradwardine seems to be partly inspired by Ockham's idea of God's absolute power. The Averroism of John of Jandun followed a middle course. A positive doctrinal contrast to those trends is to be found in the speculative mysticism of Eckhart (1260?–1328?) and his followers; by reviving the Neoplatonic doctrines of the unity of the real, of the negative nature of individuality and of the inherent need for every thing to annihilate itself in God, they strongly influenced later German philosophy.

"Free" inquiry into metaphysical issues was accompanied by new developments in several sciences and sectors of philosophy. These included formal logic (Albert of Saxony) and the mental grammar of the *modi significandi* (Thomas of Erfurt); the doctrine of the independence of political life from ecclesiastical power and of the right of citizens to choose their rulers (Ockham, Dante Alighieri, and Marsilius of Padua); the theory of "impetus" and the numerical interpretation of qualitative changes (Jean Buridan, Thomas Bradwardine, and Nicole Oresme); and the study of the nature of money (Oresme).

In the 15th and 16th centuries the main trends of thought of the 13th and 14th (Thomism, Scotism, nominalism) were kept alive in the schools (hence the term "scholasticism"); but Platonism and the idea of life as animating all things in nature inspired, outside the schools, more original thinkers. A restatement of Neoplatonism, bordering on mysticism and foreshadowing idealism, accompanied by a penetrating analysis of the incongruities of the traditional doctrines of definition and noncontradiction if metaphysically applied to things, was presented by Nicholas of Cusa (*q.v.*; 1401–64); the mathematical problems of the limits of infinite series are for him examples of the *coincidentia oppositorum*. This is the fundamental rule of a world where everything somehow includes everything else, where God (the expanded, "explicit" being) can be compared with things (the contracted, "implicit" being). Together with Marsilio Ficino (1433–99), Nicholas shared Gemistus Pletho's optimistic aspiration toward a universal philosophical religion.

In the latter half of the 16th century and early in the 17th, how-

ever. Platonism was interpreted in a more pantheistic and naturalistic vein by the south Italian philosophers Bernardino Telesio, Giordano Bruno, and Tommaso Campanella. Telesio wanted to provide an explanation of nature that would start from "its own principles" and forgo all *a priori* doctrines; for Bruno, the whole world is a living "animal" that renders explicit what its essence (*i.e.*, God) contains implicitly; and Campanella professed an extreme animism (things "sense," they are because they sense: *cognoscere est esse*). Pietro Pomponazzi (1462–1525), the leading Averroist, had also tried to find in nature the solution to all problems; he thus denied the immortality of the soul. Direct concern with nature led such men as Michel de Montaigne (1533–92) to pursue detailed observation of how beings, particularly human beings, behave; and their keen sense of realities in limited spheres was accompanied by skepticism as to the possibility of solving the "great problems" of philosophy. Similar interests, coupled with knowledge of mathematics and mechanics, made of Leonardo da Vinci (1452–1519) the pioneer of the new science of nature. (*See* further SCHOLASTICISM; also AVERROISM, LATIN; CONCEPTUALISM; NOMINALISM; REALISM; UNIVERSAL.) (L. M-Po.)

III. MODERN PHILOSOPHY

More than any other intellectual discipline, philosophy derives its stimulus from events outside its own immediate sphere. Behind the rise of a new philosophy in the 17th century lay two major happenings: the Reformation and the scientific movement initiated by Copernicus (1473–1543) and continued by Kepler (1571–1630) and by Galileo (1564–1642). The Reformation had little immediate effect on philosophical speculation, for the reformers laid primary stress on faith and inspiration rather than on reason and learning; it was not till the time of Kant that Protestantism found philosophical expression. Nevertheless, by challenging the old order in the sphere of religion Luther and Calvin facilitated its overthrow in other fields. The scientific movement, by contrast, exercised a powerful and direct influence on philosophical thought almost from the first. The new scientific attitude, with its emphasis on those aspects of natural phenomena which were quantitatively comparable as opposed to those which were qualitatively different, had, it is true, been partially anticipated in Platonism; and Platonism was not only influential in the thought of the early Middle Ages but had survived as an undercurrent throughout the period when Aristotle was in the ascendant, to be revived at the Renaissance in the manner just described. The break with familiar conceptions was, however, sufficiently sharp to present an intellectual challenge of the first importance. It became imperative for thinking men to ask what were the implications of the new view of nature and to what extent they could be reconciled with existing beliefs in other fields, in particular that of religion. The great impression made by Descartes on his contemporaries owed much to the fact that he answered this question in a way which seemed to do justice to religion and to science at once. The whole of nature constituted a great machine; there was nothing in it—not even the human body—which could not be explained in mechanical terms. But the mind or spirit of man belonged to another order altogether, an order to which God also belonged, and had to be dealt with in quite another way. Hence the new science could be admitted to the community of learning without its being necessary to show religion the door.

1. Cartesianism.—The common ascription to René Descartes (1596–1650) of the title "father of modern philosophy" has been disputed by some in favour of Francis Bacon (1561–1626). Bacon's reputation rose as that of Descartes fell. The shortcomings of Descartes's philosophy of nature, cast in the form of a rigid deductive system, stood in contrast with Bacon's preoccupation with induction; and it was asked whether Bacon, a precursor of modern empiricism, had not a better grasp of the truth. In fact, however, Descartes's account of scientific method seems, despite its obvious errors, to correspond better than anything in Bacon to the procedures of the advanced physical sciences today, and historically there can be no question of the comparative influence of the two thinkers. For all his acuteness, Bacon could scarcely claim to have provided his age with a new philosophy; nor was it Bacon's ideas which, for good or ill, set the stage for philosophical discussion during the next 300 years.

Even the briefest sketch of the Cartesian system must take some account of its genesis, for Descartes is important not merely for his positive conclusions but also for the way in which those conclusions were reached. He began, in effect, as a logician. Confronted by the confusion and stagnation which characterized many forms of learning in his day, he sought a method or standard procedure for attaining to truth in the sciences. The method, closely based on mathematics, was to start from premisses of which our knowledge was "sure and indubitable" and to proceed only to conclusions clearly seen to be implied by those premisses. But though he began as a logician, Descartes did not remain long on the purely logical level. Skeptical doubts about the applicability, as opposed to the internal consistency, of scientific systems had troubled him from an early date, and it was to quieten them that he proceeded to construct a metaphysic. The skeptical arguments which, he believed, showed the untrustworthiness for theoretical purposes of all sense judgments were powerless when directed against the existence of the self; for to doubt the self was itself to affirm it, since to doubt is to think. There was thus one firm fact on which knowledge could be built. What the argument proved, however, was very limited: only the existence of the self as a thinking thing, not that of body or matter. To prove the latter, Descartes maintained, further steps were required. We must first demonstrate the existence of God; then show that, if God exists, whatever we conceive clearly and distinctly must be true; finally establish that we have a clear and distinct idea of body or matter. Descartes proceeded to try to make good each of these points. The final system which emerged, incidentally thought of by its author as no more than the prelude to a comprehensive philosophy of nature, was a simple dualism of mind and matter as separate substances, a substance being defined (*Principles of Philosophy*, i, 51) as "a thing which so exists that it needs no other thing in order to exist."

Modern historians of philosophy, notably Étienne Gilson, have stressed the extent to which Descartes's thought connects with medieval ideas; and the terminology in which his views found expression was certainly often that of his predecessors. Nevertheless, it would be wrong to ignore the profound novelty of the Cartesian system as a whole. We have already seen how by his metaphysical dualism Descartes met one of the primary intellectual needs of his age, in a manner which may now seem crude but was certainly effective at the time, by assigning distinct spheres of influence to scientists and to theologians. At the lowest estimate this must be counted a service, though perhaps an unintended one, to the cause of science. But the novelty did not stop there. The method sketched in the second part of the *Discourse on Method* and worked out in more detail in the unfinished *Rules for the Direction of the Mind* was revolutionary not only in its bold refusal of the name of knowledge to whatever was capable of being doubted but still more in its author's conviction that "all the sciences are conjoined with one another and interdependent." Knowledge was one, and hence any suggestion that method should vary with subject matter could be ruled out. This conclusion stood in such sharp contrast with the Aristotelian assumptions hitherto prevalent that men forgot that in many points Descartes and Aristotle were in agreement about scientific method. But it was in the field known now as "theory of knowledge" that Descartes's thought was newest and most influential; indeed, he may be said to have discovered (or invented) the subject in its modern form. The famous arguments at the beginning of the *Meditations* provided a starting point for the many subsequent discussions of knowledge and certainty, with the respective cognitive claims of sense and reason; while Descartes's contention in the same context that he could be certain that he had ideas but not certain that anything independent of himself corresponded to them generated the celebrated problem of the external world. It is worth noting that on this and similar topics philosophers of an empiricist turn of mind accepted Descartes's statement of the question equally with rationalists, though they disagreed with his way of answering it. (*See* further KNOWLEDGE, THEORY OF.)

The power of Descartes's thought was clearly appreciated by his contemporaries and immediate successors, and it was not long before a flourishing school of Cartesians developed (*see* CARTESIANS). Of these Nicolas Malebranche (1638–1715), who gave an Augustinian or Platonic twist to Descartes's doctrine of ideas, is perhaps the most notable. Among Descartes's own contemporaries there were, however, two thinkers of major stature who would certainly not have called themselves Cartesians, though each felt the force of Descartes's ideas: Thomas Hobbes (1588–1679) and Blaise Pascal (1623–62). Hobbes, remembered today primarily for his views on politics, agreed with Descartes in his acceptance of mechanical principles of natural explanation and in his confidence in the powers of human reason; where he differed from Descartes was in believing that nothing existed except matter in motion and thus that there was no such thing as mental substance. Pascal, a genius of the first order whose contributions to mathematics, physics, and Christian apologetics were alike remarkable, found himself entirely out of sympathy both with Descartes's observations on method, which struck him as much too dogmatic, and with his metaphysical synthesis, which he thought did something less than justice to religion. In a century notable for its intellectualism Pascal had the insight to ask if intellectualism was enough; but since he was not strictly a philosopher (and indeed doubted the value of any kind of constructive philosophy), his influence on subsequent philosophical thought was small.

2. Spinoza and Leibniz.—Benedictus de Spinoza (1632–77) and Gottfried Wilhelm Leibniz (1646–1716) shared many of Descartes's fundamental assumptions as well as much of his terminology and were much preoccupied with difficulties which had arisen, inside the Cartesian system, about the relationship of mind and body, the role of sense experience in knowledge and the question of innate ideas or *a priori* knowledge, as it was later to be called. In addition, Spinoza was so far in agreement with Descartes's account of method that he attempted to set out his own philosophical conclusions in the form of a deductive system in his *Ethics*. Nevertheless, each was too original a philosopher to be described as a mere follower of anyone.

Spinoza began by accepting the Cartesian definition of substance and went on to argue that there could be only one substance, which he called indifferently God or Nature. Descartes himself had allowed that mind and matter were substances only in a secondary sense, for though each was otherwise complete in itself they each needed the concurrence of God in order to exist; God alone was "absolutely self-sustaining." Spinoza's version made mind and matter attributes of his single substance, the reality of which was, he said, presupposed by the reality of anything less than itself. God was to be thought of as a being of infinite attributes, but two attributes only, thought and extension, were known to human beings. Since each attribute was complete in itself, interaction between the mental and the material was strictly speaking impossible; but since God manifests himself in every attribute, whatever happens in one has its counterpart in all the rest. Thus to every mental event there corresponds a physical event, and vice versa.

The originality of Spinoza lay in his presenting a de-Christianized version of Cartesianism. Descartes had accepted the orthodox Christian conception of God as pure spirit endowed with will and intellect and had followed Augustine in laying particular stress on freedom of the will both in God and in man. All this disappeared in Spinozism. God was as much body as spirit, and there could be no question of his doing other than acting according to the necessities of his nature; free will was an illusion fostered by ignorance. Spinoza added that the philosopher could attain to freedom of a sort by recognizing the true nature of things and accepting it. It was in this sense that he sought to deliver men from "human bondage," as expressed in the eloquent concluding sections of the *Ethics*.

Spinoza's philosophy, though it had a semimystical side which was later to appeal to the Romantics, seemed in his own time to be dangerously close to materialism; Hume's (perhaps ironical) description of him as "that famous atheist" with his "hideous hypothesis" represented a common reaction. Certainly Leibniz, though he had known Spinoza personally as a young man, was anxious to avoid being thought to share his views. His own philosophizing can be represented as a sustained if not very successful attempt to avoid falling into Spinozism. Against Spinoza's all-embracing monism he maintained the existence of a vast number of individual substances, each complete in itself, of which the human soul was the most familiar example. These "monads" were spiritual realities and, indeed, the only realities, for material things did not in the strict sense exist; it was only at the confused level of sense perception that men took them to be real. Each monad was self-determining, the internal nature of each being the source of whatever happened to it, though thanks to God the activities of all were harmonized. Determinism was avoided (or so Leibniz thought) by distinguishing between truths of reason, which were logically necessary and therefore could not be other than they were, and truths of fact, which were contingent and depended only on God's decision to bring into existence the best of all possible worlds.

Leibniz had a mind which was at once highly acute and comprehensive in its range; on many points of detail he made suggestions which later philosophers found instructive. In some branches of philosophy, notably in logic, his ideas were revolutionary. But he was not a gifted writer, and he lived at a time when a new method of philosophizing was beginning to come in, making his own approach appear dogmatic and uncritical. Except in his native Germany, his philosophical work had little immediate effect. (*See* further BODY AND MIND; IDEALISM; RATIONALISM.)

3. Locke and the "New Way of Ideas."—The new method of philosophizing, mentioned above, owed its origin to John Locke (1632–1704). More than any other philosopher of his time Locke bridged the gap between two ages and two traditions, for though he shared much of the rationalistic outlook of the 17th century and indeed was in some respects a very conservative thinker (as witness his political theory, which falls firmly into the natural-law tradition), he even so initiated methods and procedures which were to be typical of the following century. His work led to a shift in the interests of philosophers and to a diminution in their ambitions.

Descartes, Spinoza, and Leibniz had each sought to construct an elaborate metaphysical system, and Descartes at least had hoped to make his metaphysics the basis for a speculative physics. Locke, as he made clear in a famous passage at the beginning of his *Essay Concerning Human Understanding*, was more modest. "In an age that produces such masters as the great Huygenius, and the incomparable Mr. Newton," he wrote, "it is ambition enough to be employed as an under-labourer in clearing the ground a little, and removing some of the rubbish that lies in the way of knowledge." This task could be achieved if philosophers would turn their attention from the construction of systems to the examination of ideas and to the question of their significance; in more recent terminology, to problems of philosophical analysis. It was with the analysis and clarification of the idea of knowledge that the *Essay* was explicitly concerned.

What makes this passage of special interest is that here for the first time in modern philosophy there is suggested a clear division of function between philosopher and scientist, hitherto thought of as one. But Locke's innovations were not confined to this major step. He suggested not only a task for philosophers but also a way of solving philosophical questions: by the use of what he called the "historical, plain method." This was, in effect, an appeal to experience and, in particular, to the experience of consciousness as revealed in introspection. By taking this simple step, Locke believed, men could eliminate from their thought much pretentious but unfounded dogma, for instance that associated with the contemporary doctrine of innate ideas. Men had only to look at their own thoughts to see that there was nothing to be said for that doctrine. In introducing the "historical, plain method" Locke gave a psychological twist to philosophical investigation which remained a prominent feature of the study till the beginning of the 20th century.

Locke was neither a wholly consequential nor even a very powerful thinker, yet the *Essay* proved a fertile starting point for subsequent discussion. The problem of the origin of ideas, which

so largely occupied 18th-century philosophers, was clearly stated there; and the ideas to which they gave particular attention, substance, "power" and self-identity, for instance, had all been examined by Locke. The difference between Hume and Kant about the function and status of *a priori* propositions arose, in effect, out of the treatment of knowledge in book iv. Similarly, Locke's interpretation of "reflection" as a kind of "inner sense" set the stage for later discussions of the problem of self-knowledge. On these and other points Locke may often have proved misleading, but that he was influential could not be denied. (*See* further CAUSALITY; INNATE IDEAS; PSYCHOLOGY, HISTORY OF.)

4. Sense and Reason in the 18th Century.—The 18th century, so often described as the Age of Reason, began philosophically with a sharp reaction against rationalism. The prestige of Descartes and the Cartesians slumped, partly because of the work of Locke, but still more because of the supersession of Cartesian physics by the less speculative theories of Newton. It was only in the field of mathematics, as Hume observed, that the claims of reason had been vindicated, and they were successful there because what was in question was relations between ideas, not matters of fact. For knowledge of matters of fact and of existence, experience (by which was meant sense experience) was essential.

This movement toward empiricism, as it was subsequently called, had its counterpart in the ethical sphere when the intellectualistic accounts of such writers as Ralph Cudworth and Samuel Clarke gave way to the "moral-sense" theories of the 3rd earl of Shaftesbury and of Francis Hutcheson (*see* also ETHICS, HISTORY OF). It was carried to its furthest extent when Hume declared, in his *Treatise of Human Nature*, that belief (*i.e.*, what had traditionally been called "judgment") was "more properly an act of the sensitive, than of the cogitative part of our natures." It should be pointed out, however, that despite such remarks Hume's outlook was rationalist in a different sense, insofar as he attached no importance to immediate feeling or "enthusiasm" in the sphere of religion. In this respect he and other writers of the Enlightenment (*q.v.*) did not diverge from the Cartesian tradition.

Hume's philosophy is partly built on certain theories of George Berkeley (1685–1753), who in turn was much indebted to Locke. The debt was, however, negative rather than positive, insofar as passages in Locke's *Essay* set Berkeley thinking and provided him with premisses from which he drew conclusions of his own. These conclusions principally concerned the status of the so-called "external" world. Locke, following Descartes, had held that the immediate objects of human perception are ideas in the mind, but had added that we must suppose these ideas to be caused by independently existing material things, of which we could have no direct knowledge. Berkeley showed that, given Locke's premisses, no such inference was warranted. There could be no causal inference from the occurrence of ideas to the existence of "inert" material bodies, for nothing in experience justifies us in thinking that such bodies could be causes, and indeed we had difficulty in attaching a meaning to the very idea of such entities. The only possible cause of our ideas was a "spirit." Hence Berkeley drew two conclusions: first, that the familiar things of sense must be thought of as collections of ideas, having no existence "without the mind"; and second, that we must suppose the existence of an infinite spirit who excites ideas in us and thus makes our experiences correspond.

Berkeley's philosophy was written, as the title of his *Three Dialogues* put it, "in opposition to Sceptics and Atheists"; but it is doubtful whether it ever achieved much for the antiskeptical cause. Plain men from Samuel Johnson onward have found its argument against matter paradoxical in the extreme, while its constructive side is too lightly sketched to be convincing. Historically, its main effect was on David Hume (1711–76), himself a notorious skeptic, who drew from it arguments to strengthen his own radical empiricism. The features in Berkeley on which Hume fastened were (1) his polemic against abstract ideas, which had been introduced by Berkeley to discredit the notion of material substance, but the antimetaphysical implications of which were, as Hume saw, much wider; and (2) his explanation of the causal relation as met with in nature as being no more than a relation of regular succession or, as Berkeley had it, of "sign" and "thing signified." Using Berkeley's polemic as a means of eliminating spiritual as well as material substance, Hume went on to argue that Berkeley's analysis of the causal relation was valid for all cases of causation, including the activities of human agents. All events are "loose and separate," no one happening relates intrinsically to any other. Connections between events there are, but they are external connections only, for "*A* causes *B*" means no more than, roughly, that (1) *A* precedes *B* in time; that (2) similar sequences have been observed in the past; and that (3) as a result there is a strong tendency in the mind to expect something like *B* when *A* occurs. It should be noticed that accepting this analysis of causality means recognizing that causal relations can hold only between what is capable of being experienced—a consequence which casts grave doubt on the use of the concept made by many earlier philosophers.

Hume's thought is misrepresented if we lay exclusive stress on his empiricism. There is another side to it, which he himself called "scepticism," though he used the word in a different sense from Berkeley's. The object of his skepticism was human reasoning, or rather that part of it which concerns questions of fact, the reasoning which we employ in history and in daily life as opposed to that which we employ in mathematics. Hume pointed out that all such "probable" or "moral" reasoning, as he calls it, proceeds on a principle which cannot be proved, the principle that the future will resemble the past; and he argued that because our confidence in this principle cannot be rationally justified, it must be derived from custom and habit; that is, it must have a nonrational basis. Men therefore deceive themselves if they suppose that their possession of reason makes them superior to animals, for in this all-important matter both are in precisely the same case. Outside the field of strict demonstration, human thought and animal thought proceed on the same lines. (*See* further INDUCTION; SKEPTICISM.)

These challenging observations were little appreciated by Hume's contemporaries. The *Treatise of Human Nature*, as its author complained, "fell dead-born from the press"; and the two *Enquiries*, in which Hume served up his ideas again in a somewhat emasculated form, attracted little intelligent comment. It was not till the time of Kant that the force of Hume's thinking was recognized. Meanwhile his fellow countryman Thomas Reid (1710–96) sought to answer skepticism by elevating common sense to be the criterion of philosophical truth, in a way that anticipates the work of G. E. Moore in the 20th century. The Scottish school founded by him (*see* COMMON SENSE, PHILOSOPHY OF) was, however, largely undistinguished and left little permanent mark on philosophical thought.

5. The Enlightenment, Kant and Hegel.—The most striking feature of the intellectual life of the 18th century was the way in which traditional Christian beliefs, still largely accepted by Descartes and even by Locke, lost their hold over men's minds and gave way to a different creed. There were, of course, many educated men, including some of the most eminent, such as Newton, who remained pious Christians; and indeed it was the exception rather than the rule for a man to proclaim himself an atheist or a materialist. But the atmosphere of the age, that of the Enlightenment, was hardly congenial to the claims of religion. Emphasis was everywhere laid on the need for tangible evidence and for clarity of thought, in a way hostile to anything that savoured of the mysterious. Science, which had already done so much to explain the wonders of nature, was confidently expected to proceed to fresh triumphs, and it was widely believed that these would be in the world of human affairs. Meanwhile the banishment of superstition and "metaphysics" (already a term of abuse) was an essential condition of further advance.

It is against this background that we must judge the philosophies of Kant and his successors. Kant himself was in many respects a child of the Enlightenment; he shared its great respect for science and sympathized with its humanist ideals. But he emphatically protested, in the name not so much of religion as of morality, against the prevailing tendency toward naturalism. The belief of the *philosophes* that the moral nature of man could be

compassed in scientific terms was, he maintained, plainly false. His successors, notably Hegel, went further. Living at a time when Romanticism was in the ascendant, they put forward radical criticisms of the Enlightenment's whole outlook, alleging that its intellectualism stood condemned for utter failure to do justice to the rich individuality of things as we are immediately aware of them, and demanding a more adequate philosophy that should do just this. Yet it is notable that Hegel at least did not propose to turn the clock back to the simplicities of a prescientific age; if he questioned the omnicompetence of science, this did not blind him to its achievements. Whatever defects the Enlightenment's ideal of clear and precise thinking might have, it was no remedy to proceed to the opposite extreme and abandon the attempt to think altogether. Mere feeling was as one-sided and inadequate as mere thought.

Immanuel Kant (1724–1804) was a student at Königsberg at a time when the prevailing philosophy in the German universities was that of Christian Wolff (1679–1754), a follower and popularizer of Leibniz. Kant, however, had the good fortune to be introduced by his teachers not only to the ideas of Leibniz but also to those of Newton, whom he never ceased to admire. His early work was as much scientific as philosophical, and though the balance of his interests shifted later he continued to follow scientific developments with close attention. Philosophically, he was influenced by Hume as well as by Leibniz, while Jean Jacques Rousseau, with his emphasis on the priority of the moral over the intellectual nature of man, also affected his thought decisively. His development was slow; it was not till the 1760s that he began to write philosophical essays of importance and not till 1781 that his first major work, the *Critique of Pure Reason,* was published. Thereafter he poured out an astonishing series of treatises on a wide variety of philosophical topics. His ideas were, more often than not, obscurely and pedantically expressed, but their force and originality were apparent from the first.

The aim of the *Critique of Pure Reason,* in the words of its author, was "to abolish knowledge in order to make room for faith." The declaration can easily be misunderstood. Kant was far from being antirationalist in his general outlook; on the contrary, he pointed out—indeed overemphasized—the role of reason in natural science and questioned its pretensions only when employed outside what he thought to be its proper sphere. The target of his polemic, in fact, was metaphysics, understood as a study which claimed to give knowledge of a suprasensible world. There were three issues, Kant declared, which were of fundamental concern to human beings: the existence of God, the freedom of the will, and the immortality of the soul; and metaphysicians claimed to deal with each of these burning topics. Unfortunately for their pretensions, however, they had never been able to establish anything definitive on any one of them, and the time had now come, Kant thought, to make clear why they never had and never could. The truth was that such questions were beyond the competence of human reason, which could be put to work effectively only when it had empirical data on which to operate and could continue to function properly only if it remained within the sphere of experience. Since God and the soul as discussed by metaphysicians were not objects of experience, reason could decide neither for nor against them. But Kant did not draw the conclusion, as some later philosophers have done, that all talk about such topics must be meaningless; he argued rather that belief in God, freedom and immortality, though not capable of justification on intellectual grounds, was nonetheless necessary for moral purposes. The moral agent, whether conscious of it or not, acted as if he accepted these beliefs, and indeed his actions made no sense without them. Thus morals or "practical reason," as Kant called it, filled the gap which critical scrutiny of the pretensions of speculative reason had revealed. (*See* further Ethics, History of.)

Kant is important historically not only for his attempt at a large-scale synthesis but also for many of his detailed suggestions. He succeeded in sharpening many old issues and in bringing to the fore many new ones. Thus his dichotomy of analytic and synthetic judgments, with the accompanying attempt to show that there are judgments which are at once synthetic and *a priori,* made possible a fresh treatment of the problem of innate ideas in the celebrated doctrine of categories, while his stimulating handling of the concept of teleology in the *Critique of Judgment* both illuminated old controversies and revealed fresh problems implicit in the language of the newly developing science of biology. For better or worse, his philosophical vocabulary affected the usage of philosophers for the next century and longer. His introduction of the notion of a "transcendental" argument, alleged to be neither deductive nor inductive, was part of an attempt to distinguish clearly between philosophy and the empirical and exact sciences; if not wholly successful, it nevertheless called attention to logical questions which previous philosophers had overlooked. (*See* further Category; Transcendentalism.)

Kant wrote his main works at a time of intellectual ferment in Germany, and his ideas had scarcely been made public before they were criticized by his younger contemporaries. The cautious empiricist strain in his disposition, his antipathy to speculation which could not be tested by evidence, his liking for cut-and-dried formulas and sharp dichotomies—none of these were to the taste of a generation already infected with Romantic ideals. Johann Gottlieb Fichte (1762–1814), who at first claimed to be his disciple, developed Kant's ideas in a way that tended to play up the role of the *a priori* factor in knowledge, which Kant had recognized but strictly circumscribed, and to play down that of the empirical element. F. W. J. von Schelling (1775–1854) carried the same tendency further and at the same time attempted a fresh metaphysical synthesis, in which the idea of life was made central at the expense of the mechanical concepts on which Kant had laid particular stress. Neither of these writers made much of a lasting impression, however; the thought of both was too lightly sketched to bear serious examination. It was not long before both were superseded in the public eye by Hegel.

The reputation of G. W. F. Hegel (1770–1831) has varied more than that of any other major philosopher. Admired almost to the point of adulation by some of his contemporaries, he has subsequently been denounced as guilty of almost every intellectual crime. A metaphysical word-spinner, seeking to replace clear thinking and patient empirical inquiry by alleged speculative insight and intuition; the father of political Fascism and the grandfather of political Communism; an enemy to science and the patron of obscurantism: these are among the descriptions which have been applied to him. In fact his views were often sober in comparison with others current at the time; they were not deliberately obscurantist though they were often obscurely expressed; and if they were opposed to the intellectual and political ideals of the Enlightenment, the opposition was openly avowed and an attempt made to offer a rational justification of it.

The basis of Hegelianism, as already indicated, lay in a contrast between life as immediately experienced and thought as commonly conceived in the generation immediately preceding Hegel's own. Like Schelling, Hegel was opposed to the mechanical interpretation of nature favoured by the physicists and by Kant; but his philosophy was not biologically centred as Schelling's was. The models from which he drew his key notion of a whole which combines unity with self-differentiation were rather, as his early writings show, certain human experiences and institutions; it is notable that his earliest criticisms of Kant were not of the latter's general philosophy but of his ethics. Hegel held that a more adequate logic than the logic of tradition was needed to think the world as it really is; and he believed that he had found the key to such a logic in his dialectical principle. Traditional logic applied only to the operations of the understanding (illustrated *par excellence* in the thinking of natural scientists), which certainly had their uses but could issue only in abstractions; dialectical logic alone was sufficiently supple to do justice at once to the similarities and to the differences of things.

Hegel was a great systematizer; and one result of his work was to reverse, temporarily at any rate, that tendency to make a modest estimate of philosophy's competence which had set in with Locke. The Hegelian philosopher, like Plato, took all knowledge and all existence for his province. What is more, Hegel was not content simply to affirm this as a matter of principle; he himself had con-

siderable knowledge in many diverse fields and brought his philosophical theories to bear on all of them. Not surprisingly, the degree of success that he achieved in attempting a uniform philosophical interpretation of a wide variety of phenomena varied; he himself showed more understanding in some fields than in others, and his principles (which sprang from reflection on particular conceptual schemes) could not be applied with equal facility to all types of material. Later critics have tended to fasten on those parts of his system, philosophy of nature in particular, in which he was least successful. From the historical point of view, however, it is well to stress not these, where his influence was negligible, but rather his writings on such topics as religion, law, aesthetics and history, where he often displayed real insight and where his detailed suggestions have proved of interest even to those who disagree with his philosophy. (*See* further ETHICS, HISTORY OF.)

6. 19th and 20th Centuries.—Philosophy after the death of Hegel no longer presents the spectacle of order which it is possible to discern without undue distortion in the thought of the two preceding centuries. There were a number of reasons for this state of affairs. One was quite simply that, in the rest of the 19th century at any rate, no major thinker of outstanding originality arose to dominate the philosophical scene. Men of ability worked at the subject, but they mostly followed one of the existing traditions rather than try to branch out on lines of their own. The fact that many of them were professional teachers in universities, well acquainted with the work of past philosophers, may be partly responsible for this. At all events it is noteworthy that the publication of Charles Darwin's *Origin of Species* in 1859, while it had its philosophical repercussions, led to no development of importance inside philosophy in the way in which Galileo's work had led to Descartes and Newton's to Kant.

A further factor was the increasing effect of national differences on philosophical practice. Descartes, Spinoza, and Leibniz were men of international repute, who had their correspondents in most of the countries of western Europe; that one was a Frenchman, one a Netherlands Jew, and the third a German had little importance. But by the end of the 18th century the most original and significant contributions to European philosophy were being made by men who wrote a language which few outside Germany could understand and whose background included elements, such as German mysticism, which were certainly not the common possession of the whole continent. The result was not only that Kant and Hegel won little general appreciation in their own lifetimes, but, more serious, that philosophers in different countries tended to conceive of their subject on widely different lines. While Germans tried to construct elaborate metaphysical systems, Frenchmen carried on the Enlightenment tradition of empirical psychology as practised, for instance, by Condillac, and Englishmen engaged in philosophical analysis in the manner of Locke and Hume. There was indeed, as the remainder of this article will show, a good deal of cross-fertilization among these different strains; yet, to speak broadly, the divergences remained and indeed were still to be found in the middle of the 20th century.

It will be possible here to give only the briefest of sketches of some of the main philosophical currents after Hegel.

Hegelian Influence.—The system of Hegel came under sharp attack within a few years of its author's death, yet Hegelian ways of thinking were persistently influential throughout the 19th century. The notion that philosophy is a synoptic study appealed to the age, and there were many attempts, by writers who acknowledged no debt to Hegel as well as by professed Hegelians, to construct metaphysical syntheses. Herbert Spencer (1820–1903), who tried to apply the concept of evolution throughout the sciences, may be mentioned as belonging to the first class; even Auguste Comte (1798–1857), despite the hostility to metaphysics which was so prominent a part of his "positive" philosophy, recalls Hegel in his attempt to present a unified picture of the whole of knowledge and in trying to find a law of development in history. Comte's preoccupation with the social sciences also has its parallel in Hegel. The "dialectical materialism" of Karl Marx and Friedrich Engels is easily the most celebrated system to admit indebtedness to Hegel, though few non-Communists have ranked it high from the purely philosophical point of view. Among more academic thinkers who continued the Hegelian tradition or felt Hegel's influence may be mentioned Thomas Hill Green, Francis Herbert Bradley, Josiah Royce, Alfred North Whitehead, Henri Bergson, and Benedetto Croce (*see* further NEO-HEGELIANISM).

The 19th century admired Hegel as a system builder; it regarded his *Encyclopaedia of the Philosophical Sciences*, which summarized his completed philosophy, as his masterpiece. But after 1905, when Wilhelm Dilthey published his pioneer study of Hegel's philosophical development, interest shifted to the *Phenomenology of Mind*, which Hegel described as his "voyage of discovery." It was the less abstract and less systematic Hegel of this work who proved philosophically stimulating in the middle decades of the 20th century. The stimulus was not confined to professing Hegelians, but affected writers as remote from Hegel in their general position as the existentialist Jean Paul Sartre and the Marxist György Lukács.

7. Empiricism, Logical Analysis, and Linguistic Philosophy.—Throughout the period of the Romantic movement and its philosophical counterpart there were philosophers in Great Britain and France who remained true to the ideals of the 18th century. Jeremy Bentham (1748–1832), whose main debts were to the associationism of David Hartley, to C. A. Helvétius and, through these two, to Hume, is only the best-known example. His follower James Mill (1773–1836), more important as a philosopher if less noteworthy for his practical influence, is another instance. The Benthamites as a group were strongly rationalist in their outlook; they were also passionately convinced that mental phenomena can all be explained in natural terms. They could see only confusion, or worse, in talk about philosophy's needing to engage in "transcendental" arguments, or in attempts to distinguish the faculties of reason and understanding: as a contemporary said, the Germans were "metaphysically mad."

Bentham and James Mill would doubtless have described themselves as empiricists, yet neither contributed much to the theory of empiricism (Bentham was primarily interested in ethics and politics and Mill in psychology). James Mill's son John Stuart Mill (1806–73) is more notable in this connection. J. S. Mill's *System of Logic* (1843) contains a fairly comprehensive restatement of the case for empiricism, as well as an attempt to work out the inductive logic which he thought to be of far greater utility than the deductive logic of tradition. Mill had little difficulty in exposing the hollow character of the "intuitions" on which his opponents, whose affinities were with the Scottish school, mostly relied; but the case that he made out for his own positive principles was far from watertight, as Bradley and others were later to show. It is astonishing, indeed, that he could have written so naïvely with the discussions of Hume's *Treatise* before him. (*See* further INDUCTION.)

Mill's conception of deductive logic was wholly conservative; he equated "ratiocination," as he called it, with syllogism and took his account of syllogism, on the formal side at least, entirely from Aristotle. The rest of the century, however, saw considerable changes in the state of formal logic, changes which, in time, had important philosophical repercussions. George Boole (1815–64) in his *Mathematical Analysis of Logic* (1847) began a process which served to bring out the restricted and incomplete character of the common textbook account of deduction. The essentials of truth-functional logic, which is altogether more comprehensive than the syllogistic logic of tradition, were formulated by Gottlob Frege (1848–1925), who also instituted important inquiries into the foundations of mathematics, arguing that the concepts of arithmetic can be reduced to those of logic. Frege made little immediate impression, partly because of clumsy symbolism, but the importance of both sides of his work was seen by Bertrand Russell (1872–); and the three volumes of *Principia Mathematica* which Russell published with A. N. Whitehead in 1910–13 both consolidated the revolution in logic and attempted to extend Frege's "logicist" thesis about arithmetic to the whole of mathematics. (*See* LOGIC, HISTORY OF.)

Principia Mathematica more than any other work gave impetus to the empiricist, analytic, and linguistic movements which were so prominent a feature of philosophical life in the English-speaking

countries in the next 50 years (elsewhere it had little important effect, except on the short-lived "Vienna circle"). It fostered the impression that the speculative philosophers of the past had based their ambitious constructions on bad, because wholly inadequate, logic; and it offered a dazzling example of a different mode of philosophizing, in which concepts were rigorously analyzed and scientific authority claimed for the results. Furthermore, by insisting on differences between the grammatical form of statements and their "underlying" logical form, it focused attention on the importance of language and raised the question whether it would not be desirable for philosophers to devise a logically perfect language if they were to avoid ambiguity and error.

Analytic and linguistic philosophers came to be divided into two main groups. One, which derived from Russell himself and claimed support from the enigmatic *Tractatus logico-philosophicus* of Ludwig Wittgenstein (1889–1951), was especially strong in the United States: it was avowedly empiricist and interested above all things in clarifying the concepts of science; and its pursuit of unambiguous expression led it to set store by formalized languages like that of mathematics and to find fault with everyday language as vague and inexact. The other group, predominant in Great Britain, owed most to George Edward Moore (1873–1958), who had defended common sense against the skeptical doubts of philosophers, and to Wittgenstein's later work, embodied in his posthumous *Philosophical Investigations*. There Wittgenstein argued, in a way which recalled Burke's defense of established political institutions, that natural language is a complex structure which is "in order as it is" and stands in need of no philosophical reform. The puzzles which philosophers raised, about meaning for example, depended on misconceptions which a closer look at the actual workings of language would dissipate. Wittgenstein wrote as if philosophy could henceforth be no more than therapeutic, but his own work included striking, if informal, analyses of a wide range of ideas which had figured in traditional theory of knowledge, and its immediate effect was to stimulate fresh discussion, particularly in the field of philosophy of mind. A central feature of this discussion was a tendency in those taking part to move away from the dualism of mind and body preserved in classical empiricism toward a position akin to that of the pragmatists. (*See* further Logical Positivism.)

Pragmatism and Antirationalism.—Where a British philosopher calls himself an empiricist, an American tends to call himself a pragmatist. Not that pragmatists would allow an absolute antithesis between the two. William James (1842–1910), who did most to put pragmatism on the philosophical map, described himself as a "radical empiricist"; and C. S. Peirce (1839–1914), who invented the word "pragmatism," not only shared the common empiricist interest in natural science but had a far better grasp of scientific procedures than any of his British contemporaries. Historically, the difference between the two doctrines rests on the fact that, whereas British empiricism looks straight back to the 18th century, American pragmatism, despite James' suspicion of Bradley with his "block universe," clearly owes a debt to Hegel. The debt comes out in the distrust of formal logic shown by such a writer as John Dewey (1859–1952) and in the related refusal to consider concepts and statements in isolation from the contexts in which they are used. The Hegelian polemic against the "abstractions" of the pure understanding reappears here.

There is a further and more substantial difference which deserves to be noted. The British empiricists, from Locke to Russell, tended to assume with Descartes (and for that matter with Plato) that there are always two distinct components in knowledge: the knowing subject and the known object. They agreed with Descartes again that knowledge ideally occurs where the subject, which they identified with mind, is in the presence of, or directly acquainted with, the object, so that the latter can be grasped by the former. The whole operation is conceived as passive, like seeing: the object imprints itself on the mind without effort on the mind's part. This analysis is decisively rejected by pragmatists. The typical cognitive situation for them is one where an animate body seeks through its sense organs to learn about its environment, with a view to acting on it later. A living thing is most truly itself not when it is passive but when it is doing something, with the result that knowledge is an activity and, for that matter, an activity of the whole organism. It should be obvious that this divergence brings to light a profound contrast of metaphysical outlooks, a contrast which may even reflect a significant difference of national temperaments. (*See* further Pragmatism.)

James is sometimes described as "anti-intellectualist" because he said that men's "passional and volitional" natures were, in certain circumstances, entitled to consideration when it was a question what to believe; the same charge was brought against Henri Bergson (1859–1941) for arguing that the intellect is a practical instrument which distorts the nature of fact even if it distorts it to good biological purpose, and for maintaining that the road to ultimate truth must accordingly be through "intuition." Later thought, however, showed a more thoroughgoing antirationalism than is to be found in either of these writers. Soren Kierkegaard (1813–55), a Danish theologian, had developed a bitter criticism of what he took to be the panlogism and optimism of his older contemporary Hegel. The notion that reality can be comprehended by reason, however refined that faculty was taken to be, broke down in face of the facts, for there were elements of the "absurd" in the real world which could not be fitted into any tidy intellectual scheme. It was decision, Kierkegaard argued, which introduced these elements. No amount of comprehension of the facts of a situation would make a man's mind up; a man had to commit himself when he made a decision, and his doing so was a leap in the dark which at once affirmed his existence and could not in principle be predicted. Kierkegaard had little influence in his own time or immediately after (though some of his views have parallels in the thought of Arthur Schopenhauer and Friedrich Nietzsche); but the rediscovery of his work in the 20th century gave his outlook wide currency. The German philosopher Martin Heidegger (1889–), the first part of whose obscure but original work *Sein und Zeit* appeared in 1926–27, was profoundly affected by him; and it is from the thought of Kierkegaard and of Heidegger that the various existentialist philosophies which were so popular on the continent of Europe immediately after World War II drew most of their ideas.

Randall, *The Career of Philosophy* (1962).

PHILOSTRATUS, the name of at least three members of a family of ancient Greek writers. They are often confused, and the attribution of certain works among them is controversial.

Flavius Philostratus (*c.* A.D. 170–*c.* 245), called "the Athenian," born perhaps in Lemnos, studied at Athens, and some time

after 202 entered the circle of the philosophic Syrian empress of Rome, Julia Domna, whom he probably accompanied on her travels. On her death he settled in Tyre. He wrote the *Gymnasticus* (a treatise dealing with athletic contests); a life of the Pythagorean philosopher Apollonius of Tyana (*q.v.*); *Bioi sophiston* (*Lives of the Sophists*), treating both the classical sophists of the 5th century B.C. and later philosophers and rhetoricians including some members of the second sophistic movement near to his own day; a discourse (*Dialexis* ii) on nature and law; and the epistles ("Love Letters") of which the 32nd (in the Loeb edition) forms the basis of Ben Jonson's "Drink to Me Only with Thine Eyes." Flavius Philostratus may have been the Philostratus who wrote the *Heroicus*, a dialogue about the cult of Protesilaus, and the dialogue *Nero* wrongly included among the works of Lucian, but these are sometimes attributed to other members of the family.

PHILOSTRATUS (b. *c.* A.D. 190), called "the Lemnian," son of Nervianus, son-in-law of Flavius Philostratus, was the author of a letter to Aspasius of Ravenna (*Dialexis* i) and of the first series of the *Imagines* in two books, discussing 65 real or imaginary paintings on mythological themes in a portico at Naples. They are an important source for the knowledge of Hellenistic art and roused the enthusiasm of Goethe who wrote an essay on them in 1818 entitled *Philostrats Gemaelde*, but they are not now regarded as providing serious artistic criticism.

PHILOSTRATUS (late 3rd century A.D.), called "the Younger," grandson of "the Lemnian," wrote the second series of 17 *Imagines*.

BIBLIOGRAPHY.—All works ed. by C. L. Kayser in the Teubner Series, 2 vol. (1870–71); *Imagines*, first series, ed. by O. Benndorf and C. Schenkl in the Teubner Series (1893); *Imagines*, second series, ed. by C. Schenkl and E. Reisch in the Teubner Series (1902); *Gymnasticus* ed. by J. Jüthner with German trans. (1909). Text with Eng. trans. in the Loeb Series as follows: *Life of Apollonius of Tyana* by F. C. Conybeare, 2 vol. (1912); *Lives of the Sophists* by W. C. Wright (1921); *Imagines* by A. Fairbanks (1931); *Letters of Alciphron, Aelian and Philostratus* by A. R. Benner and F. H. Fobes (1949). On the problem of the Philostrati, K. Münscher, "Die Philostrate," *Philologus*, Supplement 10 (1907), is fundamental. (G. B. KD.)

PHILOXENUS (AKSENAYA) OF MABBOG (d. A.D. 523), one of the best Syriac prose writers and a vehement champion of Monophysite doctrine, was born of Persian parentage at Tahal in the district of Beth Garmai east of the Tigris. He was educated at Edessa and soon attracted notice by his strenuous advocacy of Monophysite doctrine. In 485 he was made bishop of Mabbog (Hierapolis) by Peter the Fuller (d. 488), Monophysite patriarch of Antioch. Later he bitterly opposed Flavian II, Peter's orthodox successor. In 519 he was banished to Philippopolis in Thrace, and later to Gangra in Paphlagonia, where he was murdered in 523.

It was probably during the earlier years of his episcopate that Philoxenus composed his 13 homilies on the Christian life. Later he revised the Syriac version of the Bible, and under his direction his chorepiscopos Polycarp produced in 508 the so-called Philoxenian version of the New Testament, used by the Monophysites during the 6th century. Philoxenus also wrote three treatises on the Trinity and the Incarnation, tracts on Christ, confessions of faith, commentaries on the New Testament, works against the Nestorians and other heresies, prayers, and letters. Not all of these have been published.

Parvis and A. P. Wikgren, *New Testament Manuscript Studies*, pp. 32–33 (1950); A. de Halleux, *Philoxène de Mabbog* (1963). (W. D. MCH.)

PHINEUS. The most famous figure of this name in Greek mythology was a Thracian king who appears in the saga of the Argonauts (*q.v.*). They found him at the entrance to the Euxine Sea, blinded for a sin against the gods and plagued by the Harpies, who carried off or defiled his food till he was starving. In return for his prophesying the Argonauts' future course, Zetes and Calais, the winged sons of Boreas, drove away the Harpies. This is the core of the legend.

Variations occur in explaining Phineus' offense. Probably the oldest version was that by his prophecies he had revealed divine secrets. Alternatively he had blinded the sons of his first wife, Cleopatra, daughter of Boreas, persuaded by the slanders of their stepmother. (H. W. PA.)

PHITSNULOK, a province (*changwad*) and town in north central Thailand. Area 3,729 sq.mi. Pop. (1960) 351,642. The province extends from the Laos border in the northeast to the Nan-Yom River system in the southwest. The population is concentrated in the western plains, the eastern districts of Nakhonthai and Wangthong being isolated and underdeveloped. The province is a major producer of rice and has several commercial rice mills. The provincial capital Phitsnulok, pop. (1960) 30,364, is situated about 240 mi. from Bangkok on the railroad to Chiengmai, which runs along the east bank of the Nan. During most of the Ayutthayan period (1350–1767), Phitsnulok town ranked second in size and importance to the royal capital; two of the greatest kings of the era, Naresuan and Ekathotsarot, were native sons. Near the centre of the old walled city is one of Thailand's most revered Buddhist temples, Wat Phra Si Rattana Mahathat, which houses an early bronze Buddha famed for its beauty. The town's commercial centre, which lies south of the city walls, grew rapidly after the construction of the motor road to Sukhothai and Tak in the 1940s. (G. W. SK.)

PHLEBITIS: *see* VEINS, DISEASES OF.

PHLEGYAS, in Greek mythology, son of the war-god Ares and eponymous king of the savage Phlegyae in Thessaly, but also associated with central Greece and the Peloponnese. His daughter Coronis, seduced by Apollo, gave birth to Asclepius, god of medicine. Phlegyas in revenge for the seduction set fire to the Temple of Apollo at Delphi and was killed by the god. (D. E. W. W.)

PHLOGISTON: *see* CHEMISTRY: *The Phlogiston Theory*.

PHLOGOPITE, a mineral of the mica group used as an electrical insulator. Mica mined in Canada and Ceylon is mainly phlogopite, a magnesium mica differing from biotite (black mica) in containing little iron. Sometimes brownish-red and coppery in appearance, it is named from the Greek for "fiery-looking." Usually yellowish-brown, sometimes quite colourless and transparent, it often has a silvery lustre on the cleavage surfaces, hence the names "amber mica" and "silver mica" for some varieties. Phlogopite occurs chiefly as scales and plates embedded in crystalline limestones. The cleavage flakes are not so elastic as those of muscovite (white mica). In Canada it occurs with apatite in pyroxene rocks associated with Laurentian gneisses and crystalline limestones. The principal mining district is in Hull County, Quebec, and near Burgess in Lanark County, Ontario. In Ceylon the mineral forms irregular veins, rarely exceeding one or two feet in width, traversing granulite, especially near the contact of this rock with crystalline limestone. For the chemical formula and optical and other characters, *see* MICA.

PHLOX, the common and generic name of hardy perennial plants, natives of North America (one Asian), which, introduced widely in temperate-zone countries, have become favourite garden subjects. It is the typical genus of the phlox family (Polemoniaceae), and consists of about 60 species. The plants have entire, usually opposite, leaves and showy flowers, generally in terminal clusters. Each flower has a tubular calyx with five lobes, a salver-shaped corolla with a long slender tube and a flat flaring edge. The five stamens are given off from the tube of the corolla at different heights and do not protrude beyond it. The ovary is three-celled with one to two ovules in each cell; it ripens into a three-valved capsule. Many species and varieties are tall herbs yielding a wealth of bloom throughout the summer and early autumn. They require a deep, rich, rather heavy loam and a cool moist position.

J. HORACE MCFARLAND COMPANY

PHLOX (PHLOX DRUMMONDI)

The so-called blue phlox (really a mauve colour), or wild sweet william (*P. divaricata*), is found throughout the woods of east coastal, central, and southern North America.

The dwarf perennial species and varieties, the moss pinks or creeping phlox of gardens (*P. subulata*), are suitable plants for the rockery, and as edging to beds and borders. They are trailing and tufted in habit, the branches rooting at the nodes. They succeed in poorer soil and drier situations than the tall kinds. Seed is seldom produced. Propagation is effected by cuttings in July and early August (placed in a cold frame) and by division of the plants, which should be lifted carefully and cut into rooted portions as required. The tufted kinds decay in patches in winter if the situation is too moist.

Annual or Drummond phlox (*Phlox drummondi*), often called Texan pride, and its numerous varieties are annual, small-growing, hairy plants up to 1½ ft. in height, flowering profusely during the summer months. For early flowering they should be sown indoors in March and April and transferred out-of-doors in June; they succeed if sown out-of-doors in midspring, but the flowering season is later and shorter.

The tall-growing border phloxes are divided into early- and late-flowering kinds respectively, the former derived mainly from *P. glaberrima* and *P. carolina*, the latter from *P. maculata* and *P. paniculata*, both groups being common in moist woods in eastern North America. Over 200 horticultural varieties, comprising some of the finest garden perennials, have been derived from these species by selection and hybridization. Phlox come in a large variety of colours, but there are no yellows or true blues.

Since practically all the phlox species are natives of North America, with handsome representatives in every section of the United States, adoption of the genus as the floral emblem or national flower of the U.S. has been urged.

The night phlox is *Zaluzianskya capensis* and the prickly phlox is *Gilia californica*. (N. Tr.; X.)

PHNOM PENH, capital of Cambodia, is situated 125 mi. NW of Saigon at the confluence of the Mekong River and the Tonle Sap. Pop. (1962) 403,500.

According to the legend of the town's history, a woman called Penh came in the 14th century to live on the slopes of the hill (Phnom in Cambodian) overlooking the town. A bronze statue of Buddha, which she found in a tree trunk, swept to the foot of the hill during a flood and attracted a crowd of pilgrims, many of whom settled in the vicinity. In 1434 King Ponhéa Yat built his capital on the site. Subsequent kings chose Oudong, but in 1865 King Norodom I once again established the capital in Phnom Penh.

It is a picturesque town at the centre of which is the royal palace with its silver pagoda, throne room and museum. As well as archaeological museums there is the Jayavarman VII Art Museum. In the associated art school the traditional crafts of weaving and goldsmith's work are taught with modern adaptations. Mimed performances of Buddhistic and Brahminical legends are given by the Royal Company of Cambodian Dancing Girls, wearing gorgeously embroidered clothes. There are schools and a Buddhist university for Pali and Buddhist studies. Although 173 nautical mi. from the sea, Phnom Penh is a major trading port in the Mekong Valley. It is accessible all year round to shipping. Cattle, dried fish, rice, maize, cotton, and pepper are the chief items of trade. Textiles and soft drinks are manufactured. Steamers connect Phnom Penh with Saigon and many towns on the Mekong and Tonle Sap. Excellent roads lead to Saigon, Angkor, and Bangkok; Phnom Penh is also connected by road with Kompong Som, the new seaport being built on the Gulf of Siam about 137 mi. (220 km.) from the capital. There are railways to Bangkok, Saigon, and (via Bangkok) Singapore. The airport, from which services operate to Bangkok, Hong Kong, and Saigon, is at Pochentong, 5 mi. from the city.

PHOBIA, from the Greek *phobos* ("fear"), is a pathological fear of a specific object or situation. In psychiatry such (phobic) reactions are classed as a single form of the neuroses (*q.v.*), although hundreds of prefixes have been used to specify the nature of the thing feared (*e.g.*, hematophobia: fear of the sight of blood). While fear of water may be a symptom of hydrophobia (*see* RABIES), the condition is an infectious disease rather than a neurosis.

See J. R. Ewalt and D. L. Farnsworth, *Textbook of Psychiatry* (1963); S. Arieti (ed.), *American Handbook of Psychiatry*, 2 vol. (1959).

PHOCAEA, an ancient Ionic city in a sheltered bay on the northern promontory of the Gulf of Smyrna. The modern town of Foça in the *il* of Izmir, Turk., preserves its name, but little survives of its buildings. Coming late to Asia (perhaps 10th century B.C.) and possessing little arable land, the Phocaeans took to the sea and sailed the Mediterranean waters in long boats. They founded colonies in the Dardanelles at Lampsacus, on the Black Sea at Amisus (Samsun) and the Crimea, and on the Mediterranean as far west as Massilia (Marseilles) and Emporion (Ampurias in northeastern Spain); and traded with Tartessus (near Cádiz). Besieged by the Persians *c.* 545 B.C., they took to their ships; and the bolder spirits sailed to Corsica, which they evacuated after destroying the navies of Carthage and the Etruscans in a battle of annihilation. Phocaea itself was unimportant thereafter, though its captain Dionysius was chosen admiral of the Ionic fleet at Lade *c.* 494 B.C. Supporting Antiochus the Great against the Pergamene upstarts in 190 B.C., the Phocaeans so savagely repelled the Roman forces that the praetor L. Aemilius Regillus was obliged to withdraw his men and entreat the citizens not to take the war so seriously; the infuriated troops then took advantage of the truce to sack the city. After helping Aristonicus in his popular rising (132) Phocaea was sentenced to destruction by the Romans but reprieved through the intercession of its daughter-city Massilia. (Jo. M. Co.)

PHOCAS (d. 610), Byzantine emperor from 602 to 610, was a Thracian centurion in the army at the time of its rebellion against Maurice (*q.v.*) in 602. Sent to Constantinople as spokesman, he took advantage of revolts in the capital to get himself chosen emperor in place of Maurice, who was executed with his sons. Phocas' most successful relations were with Rome, where his recognition of the primacy of the apostolic see of St. Peter won him the praise of Pope Gregory I. He made peace with the Avars and in 604 agreed to pay them an increased annual tribute. He had to face the avenging forces of Maurice's ally, Khosrau (Chosroes) II, under whom the Persians pressed into Asia Minor and by 608 had reached the Bosporus. In the eastern provinces Phocas was hated because of his persecution of the Monophysites and Jews; in the capital he grew increasingly tyrannical. General discontent and fear of the Persians led to an appeal to the exarch of Carthage. In 610 the exarch sent an expedition under his son Heraclius, who had Phocas executed and was proclaimed emperor on Oct. 5, 610.

See J. B. Bury, *Later Roman Empire*, vol. ii (1889); N. H. Baynes in *Cambridge Medieval History*, vol. ii, ch. 9 (1913). (J. M. Hv.)

PHOCION (*c.* 402–318 B.C.), Athenian statesman and general, an opponent of the anti-Macedonian party of Demosthenes and others, and virtually ruler of Athens between 322 and 318. He was a pupil of Plato and in later life a close friend of Xenocrates. He distinguished himself under Chabrias in the naval battle of Naxos (376), and subsequently won the confidence of the Athenian allies by his justice and integrity. At some date (either *c.* 350 or 344/343) he served Artaxerxes III of Persia as a mercenary commander and helped to subdue a revolt in Cyprus. At Athens he was elected general 45 times in all, according to Plutarch. In 348 he saved the Athenian force operating in Euboea by the victory of Tamynae. He assisted Megara and Byzantium against Philip II of Macedonia; but he defended Philip's supporter Aeschines in 343 and was one of the envoys sent to treat with Philip after his victory at Chaeronea (338).

Phocion opposed the Lamian War which followed the death of Alexander the Great (323), though he led the defense of Attica against a Macedonian raid. The failure of the war (322) and the subsequent enforced restriction of the democracy at Athens established him as the leading man. He acted with great moderation, but in 319 he failed to prevent the Macedonian seizure of the Piraeus, and when full democracy was restored in spring 318 he was deposed. He fled to the Macedonian regent Polyperchon, but was sent back to Athens to be tried for treason and was condemned to death unheard. Shortly afterward the Athenians decreed a public burial and a statue in his honour.

BIBLIOGRAPHY.—Plutarch, *Phocion;* W. S. Ferguson, *Hellenistic Athens,* ch. 1 (1911); N. G. L. Hammond, *A History of Greece to 332 B.C.,* book vi, ch. 1, 2, 6 (1959).

PHOCIS, an ancient district of central Greece, bounded west by Ozolian Locris and Doris, north by Opuntian Locris, east by Boeotia, and south by the Gulf of Corinth (Korinthiakós Kólpos). It covered the southeastern parts of the two modern *nomoi* (departments) of Phthiotis (Fthiótis) and Phocis (Fokís) (areas 1,620 sq.mi. [4,325 sq.km.] and 806 sq.mi. [2,087 sq.km.]; capitals Lamia and Amphissa [Ámfissa]; pop. [1961] 160,035 and 47,842 respectively) and the northwest corner of modern Boeotia (Voiotía). The massive ridge of Parnassus (Parnassós; 8,061 ft. [2,457 m.]) traverses the heart of the country. Between this and the northern frontier range of Kallídhromon (4,000 ft.) is the narrow fertile valley of the Cephissus (Kifissós or Sarandapótamos) River along which lay most of the Phocian townships, including Amphicaea or Amphicleia (Amfíklia), Tithorea, Elatea (Elátia), Hyampolis (Bogdhánou), Abae (Éxarkhos), and Daulis (Dhávlia). South of Parnassus the small plains of Crisa (around modern Itéa) and Anticyra are separated by Mt. Cirphis. Phocis was mainly pastoral.

The district's early history is obscure. Its population was thought to be Aeolic, but the dialects are of the northwest Greek group, more akin to Doric. There was a tradition that the Phocians once owned land around Daphnus, opposite Euboea, and had their frontier at Thermopylae. Later restriction of territory was due to the hostility of the Boeotians and the Thessalians. The latter in the 6th century even raided the Cephissus Valley. In early days Phocians controlled the sanctuary of Delphi (*q.v.*). But about 590 B.C. a coalition of Greek states proclaimed a "sacred war," destroyed the city of Crisa, and put the sanctuary under the control of the amphictyonic council.

During the Persian invasion of 480 the Phocians at first joined in the national defense, but their irresolute conduct lost Thermopylae for the Greeks; and at Plataea they were on the Persian side. In 458 or 457 an attempt to control the headwaters of the Cephissus in the territory of Doris brought a Spartan army into Phocis in defense of the "metropolis of the Dorians." In 449 or 448 the Spartans expelled the Phocians from Delphi, but not long afterward the Phocians recaptured the sanctuary with the help of the Athenians, with whom they had become allied in 458 or 457. When Athenian land power declined, Phocian friendship waned, and in the Peloponnesian War Phocis was nominally an ally of Sparta and had lost control of Delphi.

In the 4th century Phocis was constantly endangered by Boeotian oppression. After helping Sparta to invade Boeotia during the Corinthian War (395–394), the Phocians received assistance from Sparta in 380, but afterward submitted to the growing power of Thebes. Phocians took part in Epaminondas' earlier inroads into the Peloponnese (370–366), but took no part in the campaign of Mantinea (362). In return for this negligence the Thebans secured a penal decree against them for religious offenses from the amphictyonic council (356). The Phocians, led by two capable generals, Philomelus and Onomarchus, replied by seizing Delphi and using its riches to hire mercenaries with whose help they invaded Boeotia and Thessaly, and though driven out of Thessaly by Philip II of Macedonia, maintained themselves for ten years, until the exhaustion of the temple treasures and the treachery of their leaders placed them at Philip's mercy. Their towns were split up into villages and an indemnity was exacted (346). In 339 the Phocians began to rebuild their cities; in 338 they fought against Philip at Chaeronea; in 323 they took part in the Lamian War against Antipater; and in 279 helped to defend Thermopylae against the Gauls.

During the 3rd century Phocis passed into the power of Macedonia and of the Aetolian League, to which in 196 it was annexed. Under Roman rule its league was dissolved, but was revived by Augustus, who also restored to Phocis the votes in the Delphic amphictyony which it had lost in 346 and enrolled it in the new Achaean League. The Phocian League is last heard of under Trajan.

PHOCUS, in Greek mythology, the son of Aeacus and the Nereid Psamathe who had assumed the likeness of a seal (Gr. *phoce*). Peleus and Telamon, Aeacus' legitimate sons, resented Phocus' superior athletic prowess, and at the instigation of their mother, Endeis, plotted his death, drawing lots to decide which should destroy him. The lot fell on Telamon, who murdered Phocus, feigning an accident. Aeacus, however, discovered the truth, and banished both his sons for this crime. (D. E. W. W.)

PHOCYLIDES (fl. *c.* 600 B.C.), of Miletus, Greek gnomic poet, a few fragments of whose maxims (almost all in hexameters and beginning "This too is Phocylides' ") have survived in quotations. Byzantine manuscripts also ascribe to him a poem in 230 hexameters, entitled *Gnomai,* which was composed perhaps in the 1st century A.D. by someone acquainted with the Old Testament; about 70 lines of it are also to be found in the so-called *Oracula Sibyllina* (ii:56–148). The orator Isocrates (*Ad Nicoclem* 43) mentions Phocylides along with Hesiod and Theognis as an author of "admonitions" (*hypothecai*).

See E. Diehl, *Anthologia Lyrica Graeca,* 3rd ed., vol. i (1949) for the genuine fragments and vol. ii (1961) for the spurious poem. *See* also W. Jaeger, *Paideia,* Eng. trans. by G. Highet, vol. i, 189–190 (1939).

(Js. A. D.)

PHOEBE (*Sayornis phoebe*), the name given a sparrow-sized bird of the American flycatcher family (Tyrannidae). Gray-brown above and whitish below, it perches with flirting tail and, in sudden flight, captures aerial insects. The abrupt, burry "phoebe" of the male is heard incessantly in the spring woods. Under an old bridge or overhanging ledge the phoebe builds a cup nest of mud and moss, lining it with grass and feathers; in it the three to seven white eggs are laid. The young emerge after an incubation period of 16 days and fly after an added 15 days of nest care by both parents. This species breeds in eastern North America, wintering as far south as Mexico. Say's phoebe (*S. saya*) is a western species, and the black phoebe (*S. nigricans*) lives in the southwest. (W. J. Be.)

PHOEBUS: *see* APOLLO.

PHOENICIA, in ancient geography, was the name given to a region corresponding to modern Lebanon (*q.v.*) with adjoining parts of modern Syria and Israel. Its inhabitants, the Phoenicians, occupied the mountainous area of the Lebanon and Anti-Lebanon and the seaboard between the Eleutherus River (Nahr al Kebir) in the north and Akko (modern Acre) in the south. Their chief cities (excluding colonies, for which *see* below) were Gebal (Gr. Byblos; modern Jebeil); Sidon (modern Saida); Tsur (Gr. Tyros; modern Tyre; Arabic Es Sur); and Berot (Gr. Berytos; modern Beirut), a city not mentioned before the 14th century B.C. Others of lesser importance were Simirra; Arka (perhaps Tell Arga, northeast of Tripoli); Sianu; Zarephath (mentioned in I Kings, 17:9; modern Sarafand); Achzib (Arabic Es Zib); Akko; Botrys (modern Batrun, between Tripoli and Jebeil), founded in the early 6th century B.C.; Tripolis (modern Tripoli), a colony of Tyre, Sidon, and Aradus, probably founded in the 4th century B.C.; and Orthosia, just north of Tripoli, founded in Hellenistic times. To the north lay the island stronghold of Aradus (Hebrew Arvad; modern Arwad or Ruad) (Gen. 10:18; Ezek. 27:8–11).

It is not certain what the Phoenicians called themselves in their own language. The term "Phoenician" is evidently derived from the Egyptian word *Fenkhw,* meaning an Asiatic, which is found as early as the Egyptian 5th dynasty and seems to have passed from Egyptian into Greek; but the Egyptians normally refer to them under geographical appellations, such as "Retenu." The Old Testament merely uses the city name and speaks of Sidonians or Tyrians. The Homeric poems do the same but add the name

of *Phoinikes,* "Phoenicians," which was interpreted to mean "red-skins," from Greek *phoinos,* "blood red." The only general term they would have used for themselves would appear to have been *kena'ani* (Akkadian *kinahna*), "Canaanites," a term which underlines the Phoenicians' racial identity with the pagan, pre-Hebraic population of neighbouring Palestine. (*See* CANAAN.) It is noticeable that in Hebrew the word *kena'ani* has the secondary meaning of "merchant," which well characterizes the Phoenicians. The earliest occurrence of the name is in the Akkadian form in a cuneiform inscription of the 16th century B.C. from Alalakh.

I. HISTORY

1. Origins and Relation with Egypt.—The Phoenicians probably arrived in Phoenicia *c.* 3000 B.C., although one of their native traditions, preserved by Philo of Byblos, claims that they were autochthonous. In fact excavations at Byblos itself indicate that a different population preceded the Phoenicians there in the Neolithic Period. Nothing is known of their original homeland. Classical writers (*e.g.*, Herodotus, vii, 89) preserve traditions that they came from the coast of the Red Sea (*i.e.*, the Persian Gulf), an area which excavations (*e.g.*, at Bahrain) have shown to have had a high culture at least in the late 3rd millennium B.C., in touch both with Sumer and India. But it is premature to detect there any possible ancestors of the Phoenicians. The Roman historian Justin (xviii, 3) records that the earliest Phoenicians fled from their original home because of an earthquake, pausing on the way at the "Tyrian marsh," presumably the Dead Sea, and perhaps implying an occupation of Jericho; after which they founded Sidon. This was believed to be their earliest settlement, and according to Philo it was built by a divine hero, Usoos. Some scholars have interpreted certain passages of the 14th-century-B.C. *Legend of Keret* found at Ras Shamra (Ugarit) as suggesting that the Phoenicians came via the Negev, in southern Palestine. This interpretation is not widely accepted, but discoveries of Chalcolithic settlements near Beersheba and in caves near the Dead Sea show that there were many agricultural and metalworking settlements which marked the road (and relieved its hardships) at least from the Red Sea at this period.

Except at Byblos, no excavations have produced any information concerning the 3rd millennium in Phoenicia before the advent of the Phoenicians. At Byblos, the first urban settlement (level IV, Early Bronze Age I) is dated *c.* 3050–2850 B.C. Level VI, designated as proto-Phoenician by the excavator, shows an age of prosperity already reached, the site having passed through five building levels by 2750 B.C. Commercial and religious connections, probably by sea, with Egypt are attested from the Egyptian 4th dynasty (*c.* 2613–*c.* 2494 B.C.). The earliest artistic representation of Phoenicians is found in a damaged relief at Memphis of Pharaoh Sahure of the 5th dynasty (early 25th century B.C.). This shows the arrival of an Asiatic princess to be the pharaoh's bride, in a fleet of seagoing ships, probably of the type known to the Egyptians as "Byblos ships" (see *Navigation and Seafaring*, below), manned by crews of Asiatics, evidently Phoenicians.

Soon after 2200 B.C. the Egyptian Old Kingdom was brought to an end by a movement of Asiatic nomads. Level VI at Byblos was destroyed by fire about 2150 B.C., probably by the invading Amorites (*q.v.*). The Amorites rebuilt Byblos (level VII) and a period of close contact with Egypt was begun. The fears and foreign policy of the Middle Kingdom pharaohs, particularly those of the 12th dynasty, are illuminated by the discovery of figurines representing hostile Semitic princes, which had been inscribed with their names and elaborate curses on them, then broken and thrown away; and by the discovery of costly gifts from the pharaohs to those Phoenician and Syrian princes such as the rulers of Ugarit and Qatna who were loyal to Egypt.

The skill and beauty displayed in such Egyptian imports profoundly influenced the taste and fashions of these northern courts; and the Phoenician craftsmen set themselves to imitate the elegance and ingenuity of these Egyptian works of art and to master their craftsmanship. Glazing, goldsmith's work, fresco painting, and other arts were imitated, though at first local products were somewhat clumsy.

In the 18th century B.C. new invaders called Hyksos (*q.v.*) destroyed the Amorite rule in Byblos and, passing on to Egypt, brought the Middle Kingdom to an end (*c.* 1720 B.C.). Little is known about the Hyksos' origin, but they seem to have been ethnically mixed, including a considerable Semitic element, since the Phoenician deities El, Baal, and Anat figured in their pantheon (see *Religion*, below). The rule of the Hyksos in Egypt was brief and their cultural achievement slight, but in this period the links with Phoenicia and Syria were strengthened under a single empire. When the Hyksos were finally expelled by Pharaoh Ahmose I (*c.* 1567 B.C.) he and his successor Thutmose I (*c.* 1525–1512) instituted the New Kingdom policy of conquest in Palestine and Syria. In his annals, Ahmose records capturing oxen from the *Fenkhw*, a term here perhaps referring to the Phoenicians.

Fuller information about the state of Phoenicia in the 14th century B.C. comes from the "Amarna Tablets," diplomatic texts belonging to the Egyptian foreign office, written in cuneiform and found at Tell el Amarna (*q.v.*) in Middle Egypt. Among these letters are many documents addressed by the subject princes of Phoenicia and their Egyptian governors to the pharaoh. It was a time of much political unrest. The Hittites (*q.v.*) were invading Syria; nomads from the desert supported the invasion; and many of the local chiefs were ready to seize the opportunity to throw off the yoke of Egypt. The towns of Phoenicia were divided: Aradus, Simirra, and Sidon supported the rebellion; Rib-adda, the regent of Byblos, and Abimelech, king of Tyre, held out for Egypt. But while all the towns made professions of fidelity, they were scheming for their own interests, and in the end Egypt lost them all including Byblos. The tablets which reveal this state of affairs are written in the language and script of Babylonia, and thus show the extent to which Babylonian culture had penetrated Palestine and Phoenicia; at the same time they illustrate the closeness of the relations between the Canaanite towns (*i.e.*, those in Palestine) and the dominant power of Egypt.

After the reign of Ikhnaton (Amenhotep IV; 1379–*c.* 1362), that power collapsed altogether; but his successors attempted to recover it, and Ramses II reconquered Phoenicia as far as the Nahr el Kelb. In the reign of Ramses III (1198–1166) many great changes began to occur owing to the invasion of Syria by peoples from Asia Minor and Europe, which ended in the establishment of the Philistines (*q.v.*) on the coast near Ascalon. The successors of Ramses III lost their hold over Canaan; the 21st dynasty no longer intervened in the affairs of Syria, but Sheshonk (Shishak) I, the founder of the 22nd dynasty, about 928 B.C. endeavoured to assert the ancient supremacy of Egypt (*cf.* I Kings, 14:25 ff.). His successes, however, were not lasting, and, as is clear from the Old Testament, the power of Egypt became thenceforward ineffective.

2. Assyrian and Babylonian Domination.—Between the withdrawal of Egyptian rule in Syria and the western advance of Assyria comes an interval during which the city-states of Phoenicia owned no suzerain. Byblos had kings of its own, Ahiram, Ithobaal, Abi-baal, in the 10th century, as excavations have shown. The history of this period is mainly a history of Tyre, which not

only rose to a hegemony among the Phoenician states but also founded colonies beyond the seas. Unfortunately, the native historical records of the Phoenicians have not survived, but it is clear from the Bible that the Phoenicians lived on friendly terms with the Israelites. Hiram, king of Tyre, built the Temple of Solomon at Jerusalem in return for rich gifts of oil, wine, and territory.

In the following century, however, the independence of Phoenicia was increasingly threatened by the advance of Assyria. In 868 B.C. Ashurnasirpal II reached the Mediterranean and exacted tribute from the kings of Tyre, Sidon, Byblos, and other cities. His son, Shalmaneser III, took tribute from the Tyrians and Sidonians and established a supremacy over Phoenicia, at any rate in theory, which was acknowledged by occasional payments of tribute to him and his successors. In 734 B.C. Tiglath-Pileser III in his western campaign established his authority over Byblos, Aradus, and Tyre. A fresh invasion, by Shalmaneser V, took place in 725 when he was on his way to Samaria, and in 701 Sennacherib, facing a rebellion of Philistia, Judah, and Phoenicia, drove out and deposed Luli, king of Sidon, from Tyre, forcing him to flee to Cyprus. In 678 Sidon rebelled against the Assyrians, who marched down and annihilated the city, rebuilding it on the mainland. Sieges of Tyre took place in 672 and 668, but it resisted both, only submitting in the later years of Ashurbanipal together with Manasseh of Judah.

During the period of Neo-Babylonian power which followed the fall of Nineveh in 612 B.C., the pharaohs made attempts to seize the Phoenician and Palestinian seaboard and the important land bridge between two continents which they represented. Nebuchadrezzar II, king of Babylon, having sacked Jerusalem, marched against Phoenicia and besieged Tyre, but it held out successfully for 13 years, after which it capitulated, seemingly on favourable terms.

3. Persian Period.—Phoenicia passed from the suzerainty of the Babylonians to that of their conquerors, the Persians, in 538 B.C. Not surprisingly, the Phoenicians turned as loyal supporters to the Persians who had overthrown their oppressors, and reopened to them the trade of the Orient. At the time of Xerxes I's invasion of Greece, the city of Sidon was considered to be the principal city of Phoenicia, and the ships of Sidon were considered the finest part of Xerxes' fleet, its king ranking next to Xerxes and before the king of Tyre.

Toward the close of the 5th century, Phoenician coins began to supplement historical sources. From the time of Darius I the Persian monarchs allowed their satraps and vassal states to coin silver and copper money at discretion. Hence Aradus, Byblos, Sidon, and Tyre issued a coinage of their own. The coins are stamped as a rule with the emblem or name of the city, sometimes with the ruler's name. Several inscriptions on stone of this period also exist. In the 4th century Tyre, and later Sidon, revolted against the Persian king. The revolt was suppressed in 345 B.C. In 332 B.C. Tyre resisted Alexander the Great in a siege of eight months. Alexander finally captured the city by driving a mole into the sea from the mainland to the island. As a result Tyre, the inhabitants of which were largely sold into slavery, lost all importance, soon being replaced in the leadership of the Oriental markets by Alexandria. After the cities of Phoenicia had changed hands many times between the rulers who succeeded Alexander, the Romans arrived to restore order. In 64 B.C. Phoenicia was incorporated into the Roman province of Syria, though Aradus, Sidon, and Tyre retained self-government. (For later history, *see* SYRIA: *History;* LEBANON: *History.*)

4. Constitution.—Little is known about the constitution of the Phoenician states. All Canaanite analogy speaks for kingship as the oldest form of Phoenician government. In the native inscriptions the chief of the city, in Phoenicia itself and in Cyprus, is always called king. The royal houses claimed divine descent, and the king could not be chosen outside their members. His power, however, was limited by the wealthy merchant families, who possessed great influence in public affairs. The priest of Melkarth at Tyre was the second man in the kingdom. Associated with the prince was a council of elders; such at least was the case at Byblos, Sidon, and perhaps Tyre. Inscriptions of the 3rd and 2nd centuries B.C. mention a *rab* (chief) in Sidon, Cyprus, and Gaulus; what his position was it is difficult to say; in the colonies he may have been a district governor. During Nebuchadrezzar II's reign (605–562 B.C.) a republic took the place of the monarchy at Tyre, and the government was administered by a succession of suffetes (judges); they held office for short terms, and in one instance two ruled together for six years. Much later, in the 3rd century B.C., an inscription from Tyre also mentions a suffete. Carthage was governed by two suffetes, and these officers are frequently named in connection with the Carthaginian colonies. But this does not justify any inference that Phoenicia itself had such magistrates. Under the Persians a federal bond was formed linking Sidon, Tyre, and Aradus. It was their duty to contribute 300 triremes to the Persian fleet (Herodotus, vii, 89). Federation on a larger scale was never possible in Phoenicia, for the reason that no sense of political unity existed to bind the different states together. Commercial interests dominated everything else, and while these stimulated a municipal life that was not without vigour, civil discipline and loyalty were but feebly felt. On occasion the towns could defend their independence with strenuous courage; the higher qualities which make for a progressive national life the Phoenicians did not possess.

II. COLONIAL AND COMMERCIAL ACTIVITIES

1. Colonies.—By the 2nd millennium B.C. the Phoenicians had already extended their influence along the coast of the Levant by a series of settlements, some well known, some virtually nothing but names. Well known throughout history are Joppa (Tel Aviv-Jaffa) and Dor (later Tantura, modern Nasholim) in the south. In the north, the island city of Aradus planted its colonies on the mainland opposite, beginning with Antaradus (modern Tartus). The earliest site, however, outside the Phoenician homeland known to possess important aspects of Phoenician culture is Ugarit, which was identified in 1929 in excavations at Ras Shamra, about 6 mi. N. of Latakia. The site was already occupied before the 4th millennium B.C., but the Phoenicians do not appear to have become prominent there until the time of the Egyptian 12th dynasty (1991–1786 B.C., level IV), when the position of the site as a stepping-stone to the wealth of Anatolia and Cyprus first became appreciated.

In level IV two temples first appear, dedicated to the Phoenician gods Baal and Dagon, although the ruling family appears to have been of a different, non-Phoenician stock, and the population was probably much mixed. The 15th century B.C. shows strong cultural influences already established there from Cyprus and the world of Mycenaean Greece. In the latter part of the 13th century B.C., a flood of land and sea raiders descended on the Levant coast, destroying many of the Phoenician cities and rolling onward to the frontier of Egypt, from which they were beaten back by the Pharaoh Ramses III. Ugarit was destroyed, together with Aradus and Byblos, though the latter were afterward rebuilt. Though Sidon was destroyed only in part, its inhabitants fled to Tyre, which from this time was regarded as the principal city of Phoenicia, and begins its period of prosperity and expansion.

Tradition places the founding of Utica in North Africa, Tyre's first colony, at 1140 B.C., or 1101 according to other sources. Archaeological discoveries do not today support so early a date, though some objects found there may go back to the 10th century. Similarly, the statement of Strabo (1, 48) that the Phoenicians settled at Gadir (Gr. Gades; modern Cádiz in Spain) shortly after the Trojan War has found no archaeological support. It is likely that the expansion of the Phoenicians at the beginning of the 1st millennium B.C. is to be connected with the alliance of Hiram of Tyre with Solomon of Israel in the second half of the 10th century B.C. In the following century, Phoenician influence in the north is shown by inscriptions at Sam'al (Zincirli) in eastern Cilicia, and in the 8th century at Karatepe (*q.v.*) in the Taurus Mountains. Both these cities acted as fortresses commanding the routes through the mountains to the mineral and other wealth of Anatolia. In the mid-7th century B.C. a short-lived Phoenician state was similarly established at Kundu and Sisu (modern Siz) in eastern Cilicia.

FROM D. HARDEN, "THE PHOENICIANS," 1962; THAMES AND HUDSON, LTD. AND FREDERICK A. PRAEGER, INC.

PHOENICIAN COLONIZATION IN THE MEDITERRANEAN

The great island of Cyprus early became a Phoenician colony, at least in part. A Phoenician inscription of the 9th century B.C. in the Cyprus Museum probably comes from the northeast corner of the island. The principal colony of the Phoenicians there was Citium (*q.v.*), known to the Greeks as Kition (biblical Kittim), in the southeast corner. A Phoenician text of the 8th century B.C. which was found near Amathus, and an Assyrian inscription of Esarhaddon of the 7th century, mention Qart-hadasht ("new town"), but it is not clear whether this refers to Amathus or perhaps Citium under an original name. Other sites in Cyprus, such as Idalium, Tamassus, Chytri, Lapethus, Golgi, and the site today called Athiénou, were all probably Phoenician. Others, however, such as Amathus, Salamis, and Marium may have been only partly so. Idalium itself was a Phoenician city only from the 5th century B.C., when it was captured by Citium.

Several smaller Phoenician settlements were planted as stepping-stones along the route to Spain and its mineral wealth in silver and copper. Greek tradition placed one at Cythera (an island south of the Peloponnese), but this is unconfirmed in any way. The islands of Lampas (modern Lampedusa), Cossyra (modern Pantelleria), Gaulus (modern Gozo), and Melita (modern Malta) certainly carried Phoenician trading stations, although only at Malta have early remains going back to the 7th century B.C., been found.

In Sicily the Phoenicians were established by the end of the 8th century B.C. Motya, near Marsala, has produced many Phoenician relics. According to Thucydides, the Phoenicians originally controlled a large part of the island but withdrew to the northwest corner under pressure from the Greeks. Modern scholars, however, disbelieve this and contend that the Phoenicians arrived only after the Greeks were installed.

In North Africa, the next site colonized after Utica was Carthage (*q.v.*). The Phoenicians claimed that it was occupied 287 years after Utica; *i.e.*, in 814/813 B.C. if Utica was founded in 1101. Archaeological finds made there, however, go back only to the second half of the 8th century B.C. A list of 26 sites in Tunisia bearing Punic remains has been compiled, most of them being along the coast. (The adjective Punic is derived from *Poeni*, the Latin name for the Carthaginians, derived in turn from *Phoenikes*, Phoenicians.) The finds range from the 5th to the 2nd century B.C. In Algeria the earliest is Djidjelli (7th century B.C.). In Morocco (ancient Mauretania) there are remains from Lixus (modern Larache) and Melilla and from Mogador on the Atlantic coast.

In the Balearic Islands, tradition places the earliest Phoenician colony at Ebusi (Ibiza), founded in 654/653 B.C. (*see* Diodorus v, 16, 3). The archaeological findings there, however, do not appear to date earlier than the 6th century B.C.

In Sardinia there were Phoenician sites at Nora (near Cagliari), Bosa, Sulcis (the island of Sant' Antioco, near Tortoli), and Tharros (Oristano). Inscriptions found at Tharros and Bosa have been claimed to belong to the 9th century B.C., but this is not accepted by all scholars. As far as can be seen, the material from Tharros does not go back before the 7th century B.C. at the earliest and is mostly Punic rather than Phoenician. Indeed it would appear that there was no substantial settlement in Sardinia until after the Battle of Aleria (Alalia) in about 535 B.C., which secured the island to the Carthaginians.

In Spain, the settlement of Gadir (Cádiz) at the mouth of the Guadalquivir evidently gave the settlers access to the gold, silver, and copper of Tartessus (possibly around Seville; *see* the remarkable finds illustrated by J. de M. Carriazo in *Illustrated London News*, Jan. 31, 1959). Nevertheless the earliest material so far obtained at Cádiz is regarded as not earlier than the late 6th century, though the splendid jewelry from La Aliseda is probably of the 7th century B.C.

In short, there is little factual evidence to confirm the presence of any settlement in Spain earlier than the 7th century B.C. (though for another view *see* CÁDIZ), and those settlements should be viewed as Punic rather than Phoenician, though of course it is likely that the colonizing expeditions of the Carthaginians were supported by many emigrants from the Phoenician homeland. It is in fact very probable that the tremendous colonial activity of the Phoenicians and Carthaginians was stimulated in the 8th to 6th centuries B.C. by the military blows which were wrecking the trade of the Phoenician homeland in the Levant.

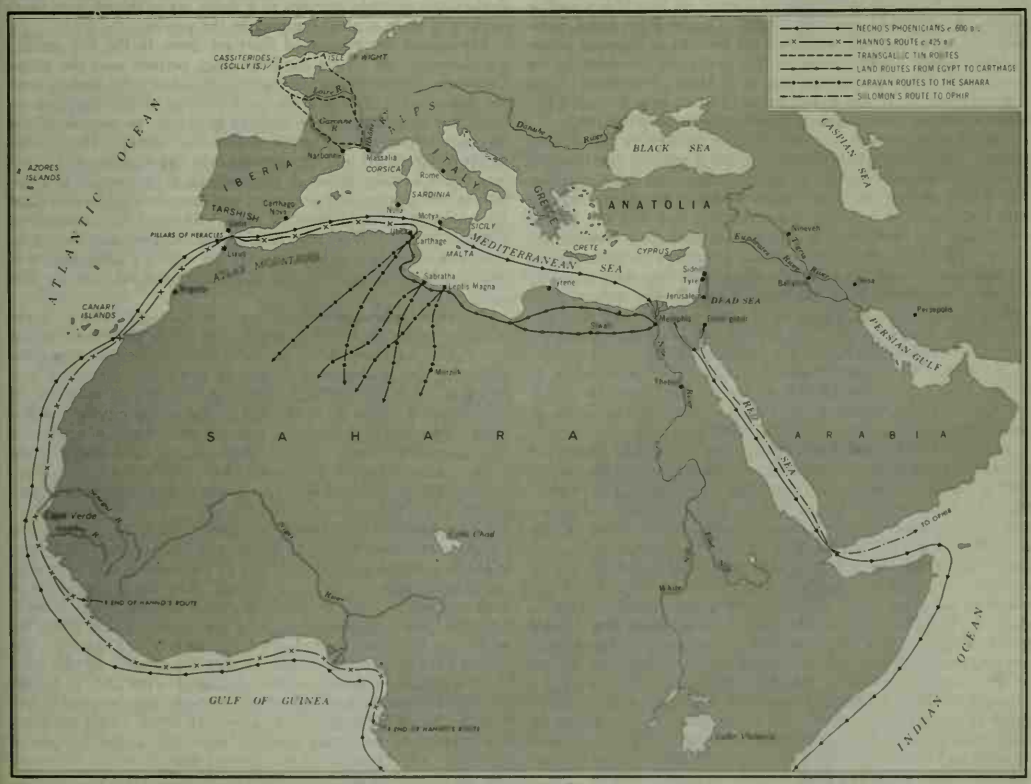
While the Greeks were repelling the invasions of the Persians and their Phoenician ally in the Aegean, the Greeks of Sicily similarly were called upon to resist the Carthaginians, and defeated them. To restore their power, the Carthaginians set up an empire in North Africa over the older Phoenician settlements. A fresh war in Sicily between 346 and 339 B.C. resulted only in a partition of the island. Carthage, led by the family of Barca, embarked on a further imperialistic phase in Spain in the following century, founding settlements at Qart-hadasht (Cartagena) and elsewhere. Carthage grew enormously, its population being claimed to reach the figure of 700,000. In 146 B.C. it was captured by the Romans, led by P. Scipio Africanus, and was totally destroyed and razed to the ground (for the history of the long preceding struggle between Rome and Carthage *see* PUNIC WARS). It was rebuilt as a Roman colony in 44 B.C. The site today lies east of the city of Tunis. Under the Roman Empire, certain of the lesser Punic cities (Leptis, Utica, Hadrumetum, Thapsus, Theudalis, Acholla, and Usula) were proclaimed autonomous. In them the ancient Phoenician language survived in use as a vernacular at least until the time of St. Augustine, bishop of Hippo (5th century A.D.).

2. Commerce.—The role which tradition especially assigns to the Phoenicians as the merchants of the Levant was first developed on a considerable scale at the time of the Egyptian 18th dynasty. The position of Phoenicia, at a junction of both land and sea routes, under the protection of Egypt, favoured this development, and the discovery of the alphabet and its use and adaptation for commercial purposes and the invention of the abacus for ready calculation assisted the rise of a mercantile society, well supplied with artisans organized in guilds and provided with slave and free labour. A fresco in an Egyptian tomb of the 18th dynasty, photographed in the 1890s and since unfortunately destroyed, depicted seven Phoenician merchant ships which had just put in at an Egyptian port to sell their goods, including the distinctive Canaanite wine jars in which wine, a drink foreign to the Egyptians, was imported. About 1100 B.C. the *Story of Wen-Amon* recounts the tale of a Phoenician merchant, Werket-el of Tanis in the Nile delta, who was the owner of "50 ships" which sailed between Tanis and Sidon. The Sidonians are also famous in the poems of Homer as craftsmen, traders, pirates, and slave dealers. The prophet Ezekiel (ch. 27 and 28), in a famous denunciation of the city of Tyre, catalogues the vast extent of its commerce, covering most of the then-known world.

The exports of Phoenicia as a whole included particularly cedar and pine wood from Lebanon, fine linen from Tyre, Byblos, and Berytos, cloths dyed with the famous Tyrian purple (made from the snail *Murex*), embroideries from Sidon, metalwork and glass, glazed faience, wine, salt, and dried fish. They carried these goods to Egypt and to the less-developed nations of Anatolia, Africa, the Aegean, and the western Mediterranean, receiving in return raw materials, such as papyrus, ivory, ebony, silk, amber, ostrich eggs, spices, incense, horses, gold, silver, copper, iron, tin, jewels, and precious stones. They established a network of trading stations and colonies over the Mediterranean shores along the route to Spain and beyond, while in the east it is possible that they found their way to India, if Ophir (*q.v.*) is to be identified with the ancient port of Supara. Hiram I, king of Tyre, and Solomon, king of Israel, formed an alliance to send a trading expedition to Ophir every three years from Ezion-geber (on the Gulf of Aqaba), and it is told that these expeditions brought back rich cargoes of gold, silver, ivory, apes, peacocks, and sandalwood (I Kings, 10:11 and 22; II Chron. 9:10 and 21). Expeditions were also sent around the coasts of Africa, and it is possible (see *Navigation and Seafaring*, below) that they reached the coasts of Britain, then called the Cassiterides, or Tin Islands, in search of the tin of Cornwall; but this rests at present only on the authority of Diodorus and Strabo and is not supported by archaeological finds.

In addition to these exports and imports, the Phoenicians also conducted an important transit trade, especially in the manufactured goods of Egypt and Babylonia (Herodotus, i, 1). From the lands of the Euphrates and Tigris regular trade routes led to the Mediterranean with trading stations on the way, several of which are mentioned by Ezekiel. In Egypt, the Phoenician merchants soon gained a foothold; they alone were able to maintain a profitable trade in the anarchic times of the 22nd and 23rd dynasties (*c.* 945–*c.* 730 B.C.). Though there were never any regular colonies of Phoenicians in Egypt, the Tyrians had a quarter of their own in Memphis (Herodotus, ii, 112). The Arabian caravan trade in perfume, spices and incense passed through Phoenician hands on its way to Greece and the west (Herodotus, iii, 107).

Between Israel and Phoenicia relations naturally were close; the



FROM D. HARDEN, "THE PHOENICIANS," 1962, THAMES AND HUDSON LTD AND FREDERICK A. PRAEGER, INC.

THE SPREAD OF PHOENICIAN TRADE AND EXPLORATION

former provided certain necessaries of life and received in exchange articles of luxury and splendour (Ezek. 27:17). After the return from the exile Tyrians sold fish and all manner of wares in Jerusalem (Neh. 13:16) and introduced other less desirable imports, such as foreign cults.

The Phoenician words which made their way into Greek at an early period indicate the kind of goods in which the Phoenicians traded with the west, or made familiar through their commerce. Some of these may well prove in the light of future study of the Minoan Linear B script to have been endenizened in the Greek language as early as the Late Bronze Age. Examples of these Semitic words in Greek guise include words for various sorts of textiles and dress, minerals, precious stones, spices, food and drink, and musical instruments. The reflection of Phoenician embroidery, weaving, and metalwork is clearly seen in the decoration and shapes of Greek pottery of the 7th century B.C., aptly called the "orientalizing period," especially in the animal friezes and the borders of lotus and palmette patterns.

Greek architecture also was deeply influenced by Phoenicia. Both the Ionic and the Aeolic capitals (*see* CAPITAL), probably also the Corinthian capital, and in Hellenistic times the Pergamene capital of palm leaves are derived from Phoenician models, as is also the ovolo (egg-and-dart) molding. The words *bōmos* from the Semitic *bamah* ("high place"); *lesche,* meaning "hall" (Phoenician *lishkah*); and *plinthos,* "brick" (English plinth), connected with Assyrian *libittu,* must have also come by the same route. It is not always easy to pinpoint these routes exactly. Naturally, the Phoenician influence made itself most strongly felt upon Greece through Rhodes and Cyprus, where strong Phoenician settlements existed; in the latter island a hybrid Greco-Phoenician art resulted. But on the mainland and islands of Greece, no Phoenician trading station or settlement has been found. On the other hand, paradoxically, excavation has produced the remains of vigorous settlements of Greek traders, from the 8th to the 6th centuries, in the homelands of the Phoenicians; *e.g.,* at Al Mina (Poseidion) on the coast of north Syria and at Tell Sukas (Paltos) near Tripoli, a site which was being excavated by a Danish expedition in the 1960s.

The Phoenicians were not mere passive peddlers in art or commerce. Their achievement in history was a positive contribution, even if it were only that of an intermediary. In the Early Iron Age they provided the newly arisen world of the Mediterranean with both material comforts and necessities and with the artistic vocabulary and techniques in which to express their feelings and tastes. The East contributed various influences to make up the "orientalizing period," but in these the Phoenicians were probably the most important force. Oriental bronze bowls, ivories, goldsmiths' work, alabaster, glazed beads, and figurines and glass objects found in ancient sites are probably all originally either imports from or through Phoenicia or imitations of them. The extent of the debt of Greece to Phoenicia may be fully measured by its adoption, perhaps in the 9th century B.C., of the Phoenician alphabet with very little variation, and by the universal use in Greece of the Phoenician standards of weights and measures.

3. Navigation and Seafaring.—For the establishment of commercial supremacy an essential constituent was the Phoenician skill in navigation and seafaring. The Phoenicians are credited with the discovery and use of Polaris (the pole star). Fearless and patient navigators, they ventured into regions where no one else dared to go, and always, with an eye to their monopoly, they carefully guarded the secrets of their trade routes and discoveries and their knowledge of winds and currents. In the 3rd and 2nd millennia B.C. they were already building and manning seagoing ships known in Egypt as "Byblos ships." Their fleets were divided into two types—"long ships" or galleys, for speed and rapid maneuver, armed with a sharp ram at the bow and propelled by two or three banks of oarsmen (these are almost certainly what are called in the Bible "ships of Tarshish"); and "round ships" called *gōlah* (Gr. *gaulos*) for trade. Both sorts are represented on an Assyrian sculpture of Sennacherib (*c.* 700 B.C.). A third division of craft was a kind of barge called by the Greeks *hippos* because the prow was formed as a horse's head.

Pharaoh Necho II (610–595 B.C.) organized the Phoenician circumnavigation of Africa (Herodotus iv, 42). Hanno, a Carthaginian, led another in the mid-5th century. The Carthaginians seem to have reached the island of Corvo in the Azores, where a pot containing Punic and other coins was found in 1740. They may even have reached Britain, for many Carthaginian coins have been found there.

III. ART, MANUFACTURES, AND WRITING

The frescoes which enliven the walls of Egyptian tombs of important personages in the 18th dynasty show tributaries bringing as gifts vessels of precious metal and other works of art, evidently of a sort particularly prized, which were imported from the north. There is general agreement that these were Phoenician manufactures. At the same time, the royal records of the pharaohs tell of rich tribute from Syria and Phoenicia. The craftsmen of those countries evidently set themselves to work for the Egyptian market in supplying its nobility with luxury goods. The illustrations of these Asiatic imports show much humour and inventiveness: vases, to be filled with water, suggesting pools, have ducks' heads peeping out of artificial flowers, while cattle hide in thickets of papyrus. Sometimes the handles are formed in the shape of captured Asiatics. Some of the foreign craftsmen settled in Egypt, and the workmen's quarters of some have been excavated at Deir el Medineh, near Thebes. In the products of Phoenicia, Egyptian motifs and ideas were mingled with those of Mesopotamia (*e.g.,* that country's love of symmetrical groupings); from the Aegean, from Crete and Mycenae was taken the taste for galloping or flying animals. To these were added the ever-present sphinxes and griffins which were native products of the Phoenician and Syrian imagination. The Phoenicians showed special skill in fusing these various devices and symbols together in a single style, though sometimes weakening their original meaning in the process.

Throughout the history of their art down to the 6th century B.C., however, the strong Egyptian tinge persists over the native Canaanite, Semitic basis. Certain classes of objects, such as scarabs and amulets, in which the great prestige of the Egyptian religion was paramount, were modeled as closely as possible on the Egyptian originals. By the 5th century B.C., however, the achievements of Greek art and craftsmanship in the mastery of the human figure, in composition, in the conquest of perspective and representation of space and movement and emotion were so great that Phoenicia was overwhelmed by them. Thus, at the cemetery of Umm al Awamid Phoenician priests, men and women, are represented in relief in a purely Greek style, and the same is true in the satrap sarcophagi from Sidon, although the subjects are Persian.

The same hellenization took place in Carthage, where Greeks settled or were employed as slaves, and in the Hellenistic period this victory of Greek taste naturally continued even more completely, a fine example in Phoenicia being the Alexander sarcophagus. Yet, at Carthage, Egyptian influence in religious art still remained strong up to the destruction of the city by the Romans. An example of this is the splendid sarcophagus of a priestess from Carthage, carved with her figure wearing the costume of the goddess Astarte-Isis; it also appears that Carthaginian priests understood the purposes of Egyptian magic and could read the hieroglyphs until the last days of the city.

1. Architecture.—Information about this subject from excavations is restricted mainly to Byblos and Ras Shamra. At Byblos in the first urban settlement (level IV) houses consist of several rooms often attached to an initial cell. The walls, apparently of mud and wattle, were founded on stones dressed at the corners. The roofs were supported by posts placed axially and along the walls. An early sanctuary existed. In level V (2850–2750), the houses have proper foundations of split limestone. In this level the first monumental temples, that dedicated to the Lady of Byblos and that of Resheph and two others, are built, and the town is surrounded by a huge rampart. In level VII (2150–1800) the practice appears of dedicating obelisks, especially in the Temple of Resheph. (The survival of this type of dedication may be traced through Canaanite religion of the Late Bronze Age, via the miniature stelae at Hazor, to the stelae set up in vast numbers in Car-

thaginian temples and sanctuaries.) A small model of a house or temple exists, found in the foundations of the Resheph Temple at Carthage. It represents a square building with two lofty doors in each side, the doorposts of which appear to be crosshatched.

No archaeological information is yet available about the details of a Phoenician temple. At Hazor, however, in Galilee, and at Naharia in Israel, Canaanite temples have been found with a tripartite division of the ground plan of court, sanctuary, and Holy of Holies, which clearly repeats that of the 10th-century temple built for Solomon at Jerusalem and described in the Bible (I Kings 5 and 6), a passage which constitutes virtually a good description of a Phoenician temple. The most striking external feature of Solomon's Temple was the pair of pillars of bronze which stood free beside the doorway and which carried elaborate capitals decorated with "lily work." In this particular, and perhaps in many others, there is evidence that the temple at Jerusalem was modeled on the Temple of Melkarth at Tyre. The latter was very ancient, founded about 2750 B.C. according to Herodotus (ii, 44). A representation of it survives in a drawing of a lost Assyrian relief from the palace of Sennacherib at Nineveh. It shows a building which resembles the Temple of Solomon in having two floors separated by a roof with a broad cornice. Before its main doors are a pair of columns with proto-Ionic or lily-shaped capitals, standing free. These are the twin columns of gold and "emerald" which Herodotus describes as "shining with great brilliancy at night." A model shrine of terra-cotta from Idalium in Cyprus, now in the Louvre, perhaps representing the Temple of Resheph-Apollo at Idalium, has a similar pair of columns. The capitals of this type are connected with the so-called proto-Ionic capitals which have been found in excavation in Palestine.

The entrances of some shrines in Phoenicia were flanked with figures of sphinxes. Other shrines, however, were built in a purely Egyptian style, as, for example, the pair of rock-carved water shrines at Amrith.

For knowledge of the appearance of Syrian and Phoenician secular architecture in the Bronze Age it is necessary to fall back on illustrations in Egyptian art. Narrative reliefs in Egyptian temples are the principal source of information, but there also exists at Medinet Habu (Thebes) a full-scale reproduction of a Canaanite fortress, which Ramses III introduced into his temple group there. These illustrations show lofty gateway buildings with windows above the gate, and a second story surmounted by a flat roof fortified with rounded crenellations. In fact, these crenellations continued in use well into the Iron Age, examples being found at Motya. The lofty upper rooms with windows above the gate were a convenient habitation for the women and the reliefs carved on the Medinet Habu building show them used so. Such buildings were famed in Egyptian fable. In the *Story of the Doomed Prince* (possibly the origin of the story of Rapunzel) a chief of Naharain (Phoenicia) has built for his only daughter a harem with 70 windows 70 cubits above the ground, which any would-be suitor has to scale. This the visiting Egyptian prince succeeds in doing.

The brief account of Solomon's palace (I Kings 7) furnishes a link between Phoenician architecture of the Bronze Age and that of the Iron Age. It was a hypostyle hall built of cedar wood, and his harem was of colossal hewn and sawn stone and cedar wood, probably laid in alternate courses as was done at Atchana and Zincirli, the techniques surviving in parts of the Middle East until modern times. Another Assyrian relief from the palace of Sennacherib depicts a Phoenician city of palaces and imposing buildings, apparently with roof gardens. Several of the tallest buildings have upper floors lit by windows, which are closed at half their height with a balustrade supported on four columns.

A relief from the palace of Sargon at Khorsabad shows a differ-

ent type of Phoenician building. Beside a lake in wooded hills is set a kiosk, or hunting lodge, the roof supported by columns with proto-Ionic capitals. The presence of the horse-headed barge, a Phoenician *hippos*, and of officers holding Phoenician sceptres clearly indicates the location in which this building is set.

Conventional Assyrian illustrations exist of the city of Tyre perched on its island (on the bronze gates of Shalmaneser, from Balawat) and probably of Aradus also on a sculpture from Khorsabad (in the Louvre). A detailed view of the quay and seawall of Tyre in the relief from the palace of Sennacherib referred to above shows that the curtain walls between the towers are hung with shields. This agrees perfectly with the description of the city in Ezek. 27:11.

A silver bowl from Amathus in Cyprus (in the British Museum) shows a presumably Phoenician city with gateway towers undergoing assault by an enemy. Within the gateway are seen a number of beehive-shaped houses. Such houses (called *magalia*) were built by Carthaginians. A clay model of one was found at Ras Shamra. The custom of building round houses must have been imported into North Africa from the Levant, for whole villages of such houses are still found in north Syria (Neirab, Arslan Tash, etc.).

2. Funerary Architecture.—In the Middle and Late Bronze Age the inhabitants of Phoenicia and Palestine constructed tombs in the form of caves cut in the soft rock and reached by vertical shafts. At Byblos the kings of the early 2nd millennium were buried in tombs of this kind, inside a stone sarcophagus. At Ras Shamra, however, under Aegean influence, the cavern took the form of a beehive tomb of carefully hewn blocks of stone. In Cyprus this tradition of a stone-built vault continued into the 6th and 5th centuries, the cavern being regarded as a sort of underground house reproduced in stone, approached by a descending flight of steps. In a tomb at Tamassus the wooden beams of a gabled roof are clearly represented, and at Amathus and Pyla the stone doorway is surmounted by a carved gorgon's head. But some strange funerary buildings were also erected above ground; *e.g.*, the two cylindrical and dome-capped monuments at Amrith, one being flanked by figures of lions. They perhaps reflect the Phoenician circular houses. E. Renan also records a pyramidal tomb obviously inspired from Egypt. In Tunisia the well-known 2nd-century-B.C. mausoleum at Thugga (Dougga), which contained a bilingual Phoenician and Numidian inscription, represents a fusion of the Egyptian pyramidal funerary building and a Hellenistic Greek temple.

3. Sculpture.—Of monumental Phoenician sculpture in the round, hardly anything survives. At Byblos, in the Temple of Baalat, only shapeless remains, chiefly the legs, exist of large statues depicted seated or standing in the forecourt of the temple. One large statue alone is complete, showing a stocky figure of Egyptian type, wearing a kilt, the hands firmly clenched and close to the hips, advancing with the left foot in the Egyptian manner and suggesting the type of archaic Greek *kouros* statue (*see* GREEK ART: *The Greek Archaic Period* [*c. 650–c. 480* B.C.]). Its date is uncertain but probably it belongs to the Iron Age. There is a long tradition of Phoenician limestone statuary in Cyprus. A colossal figure of a deity rending a lion, from Amathus in Cyprus (in the Louvre), belongs to the 6th century B.C.

Sculpture in relief, on the other hand, has a very long tradition. The excavations at Ras Shamra have produced a number of stelae belonging to the 14th–13th centuries B.C. One shows two men wearing the wrapped-round garment of the period, apparently kings swearing a contract together. Others show deities, such as Teshub, Resheph, or El. At Byblos was found the earliest major work of Phoenician sculpture to survive, the sarcophagus of Ahiram, who is dated to the end of the 11th century B.C. This limestone sarcophagus, bearing a long inscription, has carved figures of men and lions on the lid and base, and its sides are decorated with funerary scenes showing worship of, and lamentation for, the dead man. There are (or were) traces on the lid of painting in red and blue, on the dresses of the figures. This sarcophagus obviously reproduces in stone a contemporary decorated wooden chest with carved panels, and is the earliest example of what became later the established type of Phoenician funerary furniture, continuing with little change through stone sarcophagi, such as those from Amathus and Tamassus and Athiénou (late 6th and 5th centuries B.C.) to the "satrap" and "Alexander" sarcophagi and that of the "Pleureuses" at Carthage. In the 8th century B.C., relief slabs were employed architecturally (*e.g.*, at Karatepe in the Taurus Mountains). The tradition of the relief stele persists strongly in Phoenician art. From Amrith comes the fine stele in the Louvre, showing Shadrafa swinging a lion (*c.* 8th century B.C.). From near Aleppo comes a relief of Melkarth, the god of Tyre, of similar date.

In the Persian period there was a return to Egyptian models, *e.g.*, in the stele of Yehawmilk of Byblos (in the Louvre), but from Umm al Awamid there is a graceful series of funerary stelae deeply influenced by Greek art of the 5th century. The Sidonians for a time tried to synthesize Greek and Egyptian currents of art; the sarcophagus of Tabnith, king of Sidon, substitutes idealized Greek heads as portraits of the dead on the lid of the sarcophagus, now made of Greek marble. Several of the artists employed may, in fact, have been Greeks, and it is debatable how far these works are to be strictly regarded as works of Phoenician art at all. Nevertheless, these sarcophagi were very popular among wealthy Phoenicians and are found not only at Sidon but exported also to Cyprus, Egypt, Tartûs, Motya, Malta, Carthage, and Cádiz. But it is clear that by the time Greek art had begun to flourish Phoenician art had spent itself and was quite derivative and secondary, simply employing the motifs and ideas of others. At Carthage, the decadence of the relief, a genuine Phoenician tradition, could not be more complete. By the 3rd century B.C. it was reduced to a few simple subjects (the Tinit sign, a bull, sun disk and moon crescent, etc.) coarsely scratched within a shrine.

4. Carving in Wood and Ivory.—One of the chief sources of Phoenician wealth was the much-sought-after timber of the famous cedars of Lebanon. Its beams were prized for shipbuilding and

architectural purposes, but cut into panels it could also be carved in relief. At this too the Phoenicians were skilled, probably as early as the Bronze Age. The sarcophagus of Ahiram clearly reflects a carved wooden prototype. I Kings 6 and 7 describes the use of cedar for both functional and decorative purposes in Solomon's Temple and palace at Jerusalem under the influence of the Phoenicians. No examples, however, of this type of wood carving have survived. Ivory carving, being closely related to carving in hard woods, also became a Phoenician specialty, probably before the 14th century B.C., especially for the decoration of furniture. It was then aided by the convenient presence of a local supply of ivory derived from a native Syrian breed of elephant (which, however, it soon became necessary to supplement with ivory from India and Africa). At Ras Shamra a carved round table of ivory and a group of 16 carved ivory panels was found, bearing religious or mythological scenes; they evidently formed part of the decoration of a royal, perhaps ritual, bed. Such princely furniture of ivory came into fashion in the Levantine courts and shrines at the turn of the 9th–8th centuries, and ivory couches, even "ivory houses," became a symbol of luxury and oppression and social injustice to Old Testament authors (I Kings 22:39; Amos 6:4; Ps. 45:8). Remains of such ivory furniture, in the form of carved panels, in relief or open work, and various fittings, have been found in excavations at many sites in the near east.

During those years, however, the Syrian elephant herds were hunted into extinction by the Assyrian kings, and the Phoenician cities themselves were repeatedly pillaged or taxed, their markets being sometimes ruined and their craftsmen enslaved. Thus the craft died, at least in Phoenicia. In the far west its traditions lingered a little longer in decadence probably into the 5th century B.C., examples being the ivories found at Carmona in the Guadalquivir Valley in Spain. These probably were of Carthaginian manufacture.

5. Metalwork.—At Byblos in the foundations of the Temple of Resheph (*c.* 2000 B.C.) vast numbers of dedicated metal objects were found. They showed that the wealth of Phoenicia then lay as much in exploiting copper and gold deposits, probably in the Lebanon and Cyprus, as in other forms of wealth such as the cedar and pine forests. In gold working the Phoenicians were already brilliantly skilful, as may be seen from some of the finds in the Resheph Temple. After the finds of Byblos, Phoenician goldsmiths' and metalsmiths' work is well represented by two splendid gold bowls of the 14th century B.C. found at Ras Shamra, decorated with hunting and animal scenes. One of their specialties and perhaps inventions was the art of decorating a surface with tiny globules of gold to form a pattern. This art, called granulation, was later adopted by the Etruscans, on a considerable scale. But with them the secret of its technique died until rediscovered in modern times.

From Tell el Ajjul, near Gaza, comes a collection of fine jewelry of the 15th century. Some splendid Iron Age jewelry was recovered from La Aliseda (on the Guadalquivir) in southern Spain, and from Tharros in Sardinia came jewelry of the 6th century (now in the British Museum). In the poems of Homer the Sidonians are reputed the most skilful bronze workers, but it is not possible yet to ascribe such Phoenician bronzes as survive to any particular city. At Nimrud in 1847–48 was discovered a fine series of bronze engraved bowls which are probably Phoenician. Phoenician or Punic jugs and bowls of silver and bronze have been found in Spain. A spectacular account of the work of a Phoenician master craftsman and metalworker in the 10th century B.C. is that given of Hiram, who cast the great bronze pillars for Solomon's Temple at Jerusalem (I Kings 7:13–15; II Chron. 2:13). Other great works of metal-casting in the temple (I Kings 7:16 ff.) were also clearly of Phoenician inspiration, small versions of the colossal wheeled bases executed in bronze having been found in Cyprus.

6. Textiles.—Phoenician textiles were world famous. The finest linen came from Byblos, Tyre, and Berytos. The name of Motya in Sicily itself means "loom." The purple dye made from the *Murex* snail, another Phoenician specialty, made Tyrian dyed cloth famous all over the ancient world until Byzantine times. Homer describes patterned textiles (whether embroidered or woven is not clear) as a specialty of the Sidonian women (Odyssey xv, 415–418), much prized in archaic Greece. Nothing of this, however, has survived.

7. Glass.—An important part is claimed traditionally for the Phoenicians in the invention of glass, according to Pliny the Elder. This probably reflects the fact that about 1500 B.C. the manufacture of glass vessels was suddenly developed out of the age-old techniques of glasswork in the Near East, and Phoenicians possibly took an important part in this achievement. The method of manufacture was to use a sand core, decorating the surface of

dark blue with undulating lines in a lighter colour. This technique continued until glassblowing was invented. From the mid-8th century B.C. until Hellenistic times Phoenicia was very probably one of the main centres for fabricating glass.

Glassblowing was probably invented in the coastal area of Phoenicia in the 1st century B.C. or, according to some, as early as the 3rd century. During the 3rd and 2nd centuries B.C. the art of blowing into molds was evolved. Many pieces bear the artist's signature.

8. Writing.—By the second half of the 2nd millennium B.C. two systems of writing, Egyptian and Mesopotamian, both conveying only whole syllables, were in use in the Levant. The former was the hieroglyphic, with perhaps also the cursive hieratic of Egypt, but there was also an experiment in using the hieroglyphic script more or less alphabetically. The latter was the cuneiform writing. (*See* CUNEIFORM; HIEROGLYPHS.) While the Phoenicians were undoubtedly familiar with the Egyptian writing employed on stone, papyrus, or leather, they seem to have been strongly inclined to use cuneiform. The correspondence of the Egyptian chancery of Amenhotep IV (Ikhnaton) with the cities of the Levant, found at Tell el Amarna, was conducted in Akkadian written in cuneiform; and there exist many Phoenician cylinder seals (which were used only for signing clay tablets) exhibiting a mixture of Mesopotamian, Syrian, and Egyptian elements. But the Phoenicians' practical nature evidently urged them to produce a script of their own, which would effectively express the sounds of their own Northwest Semitic language and would be at once easy to write (like the Egyptian hieratic) and to learn (unlike the cumbrous Egyptian and Mesopotamian syllabaries), thereby removing its mastery from the exclusive professional monopoly of priests and scribes and breaking much of their power. Before the final alphabet was achieved there were several local experiments:

1. The "Sinaitic" or "proto-Sinaitic" script, an acrophonic adaptation of Egyptian hieroglyphs, used apparently for a Semitic script by some of the Canaanite, perhaps even Phoenician, workers in the Egyptian turquoise mines at Sarabit al Khadim in Sinai. This is largely undeciphered, except for the beginning of a dedication to Baalat on a sandstone sphinx in the British Museum. This script is dated to about 1500 B.C. (*See* also WRITING: *Phonography;* LOGOGRAM AND SYLLABARY: *Syllabic Systems: West Semitic Syllabaries.*)

2. The Ras Shamra script, discovered on clay tablets found at Ras Shamra in 1929, by the brilliant excavations of C. Schaeffer. This is a true alphabetic script of Semitic type of 30 signs, dispensing with the vowel sounds and using only consonants, written, like cuneiform, with a stylus on a clay tablet; but, though the signs are wedge-shaped, they have nothing else in common with cuneiform, and the choice of letter forms is occasionally influenced by the other alphabet of the Phoenicians. The original order in which the letters were taught is now known, and conforms to the standard order of the later Phoenician and Hebrew letters of the alphabet. The tablets which were found written with it cover myths and legends, administrative and commercial matters. Strangely enough, this script appears to be almost exclusively confined to Ugarit. (*See* also ALPHABET: *Origin.*)

3. At Byblos, in level VII (*c.* 2000 B.C.), appeared a hieroglyphic script, *sui generis,* which in fact used pictograms, though not of Egyptian derivation, and without any pictorial meaning; this script, found used on a few stone and metal documents, has been brilliantly deciphered as Phoenician by E. Dhorme.

The Phoenician script of 22 letters, purely alphabetic and abstract, purged of pictorial associations, appears at Byblos already complete by the 15th century B.C., if not earlier. M. Dunand would derive this script from an adaptation of the Egyptian hieratic. Be this as it may, this was the method of writing which was to issue from Phoenicia to conquer the world, and it is the Phoenicians' most remarkable and distinctive contribution to human arts and civilization. The fact that it is always written from right to left suggests that it was first evolved by stonemasons, holding a hammer in the right and working with a chisel in the left. But it was equally adaptable to writing with pen or brush on papyrus or leather. It is only the more to be regretted that the resultant works of Phoenician literature, written on these softer materials, have all perished, and are represented, unfortunately only in part, by the discoveries at Ras Shamra. It is recorded that Sanchuniathon of Byblos wrote nine books of mythology. There were also historical works drawn on by Menander of Tyre and others, while at Carthage works on agriculture were composed.

CLAY TABLET FROM RAS SHAMRA; IN THE BRITISH MUSEUM

A Neo-Punic script appears on funerary monuments of North Africa in the 2nd century A.D., and, though relatively uninteresting in its contents, shows from its cursive, if degenerate, forms that the art of writing the Phoenician language long survived the destruction of the empire of Carthage.

IV. RELIGION

1. Mythology and Pantheon.—The religion of the Phoenicians, as of the Canaanites in general, was inspired by the great powers and processes of nature. Many of the gods whom they worshiped, however, were localized, and are now known only under their local names. A full knowledge of the Phoenician religion is unattainable, but a greatly revised understanding of it has been made possible by the discoveries at Ras Shamra, consisting of original epics written down in the 14th century B.C. and perhaps already much older. (*See* BAAL.) These may represent the mythology of Sidon, of which Ras Shamra-Ugarit was a colony. They may be supplemented by (1) the traditions of Byblos, quoted by Philo of Byblos, in Roman times, from an author of the 13th century B.C., Sanchuniathon (humorously referred to in Goldsmith's *The Vicar of Wakefield* but now known to have been an authentic person); and (2) inscriptions and other monuments of various

dates. These show a pantheon consisting of the forces of nature, presided over by the father of the gods, El, who has Asherah of the Sea as his wife and their mother.

How are these deities depicted in art? El, according to Philo, has four wings and two faces. Such a figure may be seen on a gold ring from Aliseda in Spain, seated on a boat, presumably on the sea. He is also shown winged, in Roman coins of Byblos, of which city he was the patron god. Of his family, Baal—a mere title concealing usually the name of the widely worshiped Syrian and Canaanite storm-god Hadad (Adad [*q.v.*], Addu; known in Mesopotamia as Amurru, god of the Amorites)—is said to be the son of Dagon, the god of corn. Baal-Hadad is shown as an elder deity with a beard; *e.g.*, on the statue of Hadad of Panammu II from Zincirli. A stele from Ras Shamra shows him with club and thunderbolt, standing above the waters of the earth. Often he has, as there, a horned headdress. His son is Aliyan-Baal, a god especially of springs, wells, and fertility, who is perpetually engaged with another deity, Mot (death), in a seasonal struggle, in which, like many other similar harvest deities, he is annually vanquished and slain. In this fight he is aided by his beloved sister, the virgin, Anat. Canaanite illustrations of Aliyan-Baal are not yet known, but a series of stelae from Egypt show a nude goddess standing facing frontally, often standing on a lion and holding flowers, between a figure of the ithyphallic Egyptian god Min and a representation of the warlike Semitic deity Resheph. An inscription on one of these stelae in Winchester (England) College Museum shows that the goddess is Astarte-Anat-Qedesht (*see* ASTARTE), three forms of the same person.

Anat's companion, Resheph ("the burner"), is a war-god, shown as a bearded man, brandishing an ax, holding a shield, wearing a tall pointed headdress (a version of the Upper Egyptian crown), with a goat's or gazelle's head on his forehead. This is no doubt the Resheph—sprm, "Resheph of the Goats," mentioned in the Karatepe bilingual inscription. He is probably a form of Baal. In Egypt from the 17th dynasty he is identified with Setekh (Set), the enemy of Osiris. Resheph was worshiped at Ras Shamra, Byblos, and Arsuf (near Jaffa); under the title Mikal he was also worshiped at Beth-shan in eastern Palestine and at Idalium in Cyprus (where he is equated punningly with Apollo Amyklaios). He appears to be represented on a Carthaginian razor of late date standing beneath a star. Another bearded god of fertility, resembling Resheph, wearing a pointed hat with pendant tassel, is depicted at Utica, Sousse, and elsewhere.

A youthful, beardless god of benevolent character is Shadrafa, depicted on the stele from Amrith (in the Louvre), standing on a lion above mountains, wearing a long trailing garment and a pointed headdress, and holding a small lion in one hand and a whip (?) in the other. A similarly dressed figure appears on ivories from Nimrud and Arslan Tash, plucking fruit from the "tree of life." An approximation to Eshmun of Byblos (equated with Adonis and perhaps also to Aliyan-Baal) seems suggested. Shadrafa was worshiped in North Africa as the tutelary deity of Leptis Magna, being equated with Liber-Dionysus.

Melkarth (Melkart, Melqart), "Lord of the City," was the patron deity of Tyre, where his temple was seen and described by Herodotus (who calls it that of Heracles). As Malku, he is equated with the Babylonian Nergal, god of the underworld and death, and thus may well prove to be related to the god Mot of Ras Shamra. His appearance is attested by an inscribed stele from north Syria which shows him bearded, wearing a high rounded hat and a kilt and holding, significantly, an Egyptian ankh, symbol of life, and, as symbol of death, a fenestrated ax, a type of weapon used in Canaan in the Middle and Late Bronze Ages. This stele makes it possible to recognize him in gems of the 6th century B.C. from Tharros in which he is seen slaying a lion, and it explains his Greek equation with Heracles, the vanquisher of the Nemean lion. On a silver bowl from Praeneste he is depicted in mythological drama in which he has various adventures while hunting. At Tyre, Melkarth had an annual winter and spring festival, during which he made an epiphany between the columns of his temple when he represented the rebirth of the sun. At Carthage he was represented still in his traditional form, bearded, with high hat and fenestrated ax, on late terra-cottas. Another important centre of his cult was Gadir (Cádiz). As Baal of Tarsus, he was equated with the Anatolian god Santas or Sandon, and his burning on a pyre was annually commemorated at Tarsus in classical times. It is likely that he was thus equated with the sun. Baal Amon (Baal Hamman), "Lord of the Burning Altar," was perhaps his title in this capacity. A scaraboid from Ibiza shows him standing before an incense altar under a winged disk. A rectangular altar beneath a circular disk is depicted on a miniature altar (at the Louvre) found at Ras Shamra. It is reasonable to suppose that this is a symbol of Baal Amon. Similar rectangular altars were found at Beisan and Hazor. Baal Amon is the chief god of Carthage, consort of the goddess Tinit (Tint).

Baal Shamin, "Lord of the Heavens," is identified by Sanchuniathon with the sun. But there is reason rather to identify him more correctly with Hadad, whereas at Ras Shamra the deity of the sun is a goddess, Shapash. Possibly Baal Shamin was her consort or parent. A winged sun-goddess appears on the silver bowl from Praeneste.

The goddess Astarte (Ashtart) remains the principal figure of the Phoenician pantheon. In her virgin form she is Anat. The cycle of myth associating Astarte with Byblos as the Baalat Gebal, "Lady of Byblos," is very ancient and goes back to the Egyptian Old Kingdom, where, with her son, Eshmun, she was assimilated to Isis and her son, the child Horus, who is attacked by his brother Set. Sometimes the relationship of Astarte and Eshmun is symbolized by a group of a cow suckling a calf, and a further assimilation is made to the Egyptian goddess Hathor, whose horns and disk the Baalat Gebal wears on the stele of Yehawmilk of Byblos. Astarte is further symbolized by a sphinx, while the palm tree and various forms of the "tree of life" represent her son Eshmun. On a bronze bowl from Nimrud (in the British Museum), showing the pantheon, Astarte is shown seated beneath the canopy of stars as queen of heaven. Eshmun is a child like Horus, seated on a lotus flower. Similar scenes showing Eshmun occur on ivories from Nimrud and Arslan Tash. On an ivory panel from Ras Shamra, Astarte, wearing the horns of Hathor, suckles him when already a youth. A similar scene under a palm tree occurs on a relief from Karatepe and on a bronze razor from Carthage. In the form of the beautiful youth Adonis (as he was known to the Greeks from the Semitic *Adon*, "master") Eshmun was believed slain and was mourned annually in the Iron Age in an elaborate ritual—the Adonia—which is described by Theocritus as it was practised in Hellenistic Sicily. In north Syria he seems to have been represented differently: as a four-winged figure wearing a triple *atef* crown, holding ears of grain. This grain deity seems to have found entry through Assyria into the art of the early Persian Empire, being depicted on the doorway of Cyrus' palace at Pasargadae.

In Punic North Africa, Astarte rapidly assumed a predominant place, being worshiped with Baal Amon under the name Tanith (Tinith), "face of Baal." In Ibiza a rock sanctuary was found dedicated to her at Cueva d'es Cuyram. In terra-cottas found there she is represented partly in the form of a Greek goddess, wearing a *polos* (headdress), but with her lower body truncated and wrapped in a pair of falcon's wings, like a priestess. At Carthage, however, she is still represented in a Greek style, wearing a richly ornamented crown and heavy breast ornament. By the 3rd century B.C. she is represented uniformly aniconically, by a sign somewhat resembling an Egyptian ankh with a triangular base, probably evolved from the truncated type of figure seen at Ibiza. In Roman times, her astral capacity becomes supreme and she is called *Caelestis* or *Genius Terrae Africae*, and her consort Baal Amon is identified with Saturn. At this period, though still sometimes represented by the ankhlike symbol on Neo-Punic stelae, she is also illustrated as a woman with a lion's head and once more wearing the enveloping falcon's wings. In the worship of Tanith and Baal Amon, children, probably first-born, were sacrificed; remains have been discovered in the *tophet* at Salammbo and at Motya, at Sulcis and Tharros.

A curious design on a ring from Carthage, showing a foot sur-

mounted by a bearded head, may be presumed to represent Pumai Elioun, "Foot of Elioun." That this deity was worshiped at Carthage is shown by a dedication inscribed on a gold pendant from Douimes. He is none other than the character known to Greek mythology as Pygmalion.

From Punic and Phoenician names it is clear that the worship of Osiris, probably equated with Eshmun, was included in their cults.

2. Religious Practices.—Probably, like other Canaanites, the Phoenicians offered worship "on every high hill and under every green tree"; but, to judge from the allusions to sanctuaries in the inscriptions and elsewhere, the Baal or Astarte of a place was usually worshiped at a temple, which consisted of a court or enclosure and a roofed shrine with a portico or pillared hall at the entrance. In the court sometimes stood a conical stone, probably the symbol of Astarte, as on the Roman coins of Byblos. Stone or bronze images of the gods were set up in the sanctuaries, along with the *baetyli* (meteoric stones) which were regarded as symbols of the gods. Pillars, again, had a prominent place in the court or before the shrine, but it is not known whether the sacred pole (*asherah*), an invariable feature of a Canaanite sanctuary, was usual in a Phoenician temple. The inscriptions mention altars of stone and bronze, and from the sacrificial tariffs (lists) which have survived it is clear that the chief types of sacrifice among the Phoenicians were analogous to those found in the Old Testament. The practice of sacrificing human victims was resorted to in times of great distress (*e.g.*, at Carthage, according to Diodorus, xx, 14) or to avert national disaster (Porphyry, *De Abstinentia*, ii, 56). It was regarded as a patriotic act when Hamilcar threw himself upon the pyre after the disastrous Battle of Himera (Herodotus, vii, 167). The god who demanded these victims, and especially the burning of children, seems to have been the Moloch or Molech of the Old Testament, though according to some scholars this is the name not of the god but of the sacrifice. In this connection may be mentioned the custom of burning the chief god of the city in effigy, or in the person of a human representative, at Tyre and in the Tyrian colonies, such as Carthage and Gadir; the custom lasted down to a late time. Another sacrifice was regularly demanded by Phoenician religion: women sacrificed their virginity at the shrines of Astarte in the belief that they thus propitiated the goddess and won her favour. *See* also references under "Phoenicia" in the Index.

PHOENIX, in Greek mythology, the son of Amyntor, king of Thessalian Hellas. After a violent quarrel Amyntor cursed him with childlessness, and Phoenix escaped to Peleus, who made him responsible for Achilles' upbringing. Phoenix accompanied the young Achilles to Troy, and was one of the envoys who vainly tried to reconcile him with Agamemnon. (D. E. W. W.)

PHOENIX, capital and largest city of Arizona, U.S., and seat of Maricopa county, occupies approximately 187 sq.mi. of an arid saucer-shaped valley formed by the Salt river, midway between El Paso and Los Angeles. The city is the commercial focus of large irrigation projects, important to its growth, which are fed from the T. Roosevelt dam, 70 mi. N.E. The hub of an area of scenic grandeur, it is also a health and tourist centre.

The Salt river valley was occupied as early as 1300 A.D. by prehistoric Indians known to anthropologists as Hohokam (*q.v.*) or "the people who have gone." They developed a system of primitive irrigation canals, erected early buildings and then vanished mysteriously. An historic gap followed until the first white men came during the American Civil War. One, an imaginative prospector, Jack Swilling, noticed the visible remnants of ancient Indian canals and realizing irrigation possibilities, organized an irrigation company. Canals and harvests followed and a crude village was founded.

An associate of Swilling's, Darrel Duppa, English adventurer and scholar, was impressed by the evidences of prehistoric culture. Like the legendary phoenix which, consumed by fire, arose from its own ashes, so, Duppa predicted, would the Salt river city be born from ancient Indian ruins. Thus the settlement was named Phoenix. Incorporated in 1881, it acquired its first railroad in 1887. Phoenix, with a population of about 3,000, became the seat of the territorial government in 1889, and remained the capital when Arizona attained statehood in 1912. The city has been council-manager governed since 1914.

The economy is based on agriculture, tourism and manufacturing. The fertile Salt river valley produces long-staple cotton, forage, vegetables and fruits. Manufacturing, almost nonexistent before 1940, later became the chief source of income. Aircraft and electronic components, aluminum extrusions, air-conditioning equipment and many small manufacturing enterprises add to the economic wealth of the city.

More than 30 secondary schools and Phoenix college, a two-year college established 1920, are in the city proper. Independent school districts are in outlying communities. Parks, playgrounds, an adult recreational centre, an active little theatre, a professional winter theatre, a symphony orchestra and professional baseball provide recreational and cultural opportunities. Notable annual events are the Copper Bowl parade and football game, the World's Championship rodeo and the Arizona state fair.

The state capitol consists of an original building of native tufa and of neoclassic design, with two additional wings for the house of representatives and the senate. These buildings are set in a 10-ac. park, where trees and shrubs indigenous to the region are represented. Papago park (1,094 ac.) lies within the city limits to the east and to the south is the city's South Mountain park of 14,000 ac.

The Phoenix standard metropolitan statistical area comprising Maricopa county includes: Mormon-founded Mesa, site of the state experimental farm; Glendale, a farming community with nearby Luke air force base; and Tempe, location of Arizona State university (established in 1885 as Arizona Territorial Normal school). A post-World War II population boom, with Arizona's warm climate and clear air (85% average "possible" sunshine) as the main enticements, made Phoenix one of the fastest growing cities in the United States. Between 1950 and 1960 its population increased from 106,818 to 439,170 within the city limits and from 331,770 to 663,510 within the standard metropolitan statistical area. For comparative population figures *see* table in ARIZONA: *Population.* (Jo. S.)

PHOENIX, a fabulous bird connected with the worship of the sun especially in ancient Egypt and in classical antiquity. It was known to Hesiod, and descriptions of its appearance and behaviour occur in ancient literature sporadically, with variations in detail, from Herodotus' account of Egypt onward. The phoenix is said to be as large as an eagle, with brilliant scarlet and gold plumage and a melodious cry. Only one phoenix exists at any time. It is very long-lived; no ancient authority gives it a life

span of less than 500 years; some say it lives for 1,461 years (an Egyptian Sothic Period): an extreme estimate is 97,200. As its end approaches the phoenix fashions a nest of aromatic boughs and spices, sets it on fire, and is consumed in the flames. From this pyre miraculously springs a new phoenix, which after embalming its father's ashes in an egg of myrrh flies with them to Heliopolis in Egypt where it deposits them on the altar in the Temple of the Sun. One variant of the story makes the dying phoenix fly itself to Heliopolis and immolate itself in the fire burning on the sun's altar, a young phoenix being born from the flames.

The *bennu*, a kind of heron, is traditionally associated with sun worship in Egypt, appearing on monuments as a symbol of the rising sun and of the life after death. Classical authors who allude to pictorial representations of the phoenix almost certainly have the *bennu* in mind. But despite the etymological similarity and the common religious associations, it remains true that the phoenix as described in literature does not at all resemble a heron in appearance and that its home is not in Egypt but nearer the rising sun (normally in Arabia or India, where spices for the nest and egg were plentiful). Clearly the colouring of the phoenix, its miraculous rebirth, its connection with fire, and other features of its story are symbolical of the sun itself, with its promise of dawn after sunset, and of new life after death. Probably the phoenix story originated in the Orient and was assimilated to Egyptian sun worship by the priests at Heliopolis. The adaptation of the myth to an Egyptian environment helped to bring about the connection between the phoenix and the palm tree (also called *phoinix* in Greek). A holy tree was long associated with the worship of the sun in Egypt, and the sacred palm tree was said to live as long as the phoenix and to die at the same time.

As has been shown, the Egyptians associated the phoenix with intimations of immortality, and this symbolism had a widespread appeal in late antiquity. The Latin poet Martial compared the phoenix to undying Rome, and it appears on the coinage of the late Roman Empire as a symbol of the Eternal City. It is also widely interpreted as an allegory of resurrection and life after death. These were ideas which appealed to emergent Christianity; Church Fathers and the *Physiologus* (*see* BESTIARY) use the phoenix as an illustration of Christian doctrine concerning the raising of the dead and eternal life. Its miraculous birth was also sometimes compared to the virgin birth of Christ. The *Phoenix*, a Latin elegiac poem 170 lines long, generally ascribed to Lactantius, exemplifies the Christian attitude.

See A. Rusch, in Pauly-Wissowa, *Real-Encyclopädie der classischen Altertumswissenschaft*, vol. xx, col. 414–423 (1941). (D. E. W. W.)

PHOLIDOTA, an order of placental mammals, comprising only the scaly anteaters or pangolins of Asia and Africa. The pangolins were at one time grouped with the true anteaters, sloths and armadillos in the order Edentata, mainly because of their likeness to the South American anteaters in the absence of teeth, the weakness of the jaws, the enlargement of the salivary glands and the length of the wormlike, extensile tongue; and to the armadillos in the possession of a hard dermal exoskeleton. But the resemblances to the edentates are adaptive and due to similarity of diet and of habitat. The exoskeleton is of a totally different type from that of the armadillos, since it consists of large, erectile, overlapping horny scales, composed of cemented hairs, there being no trace of bony matter in the skin. They show no resemblances to the edentates of any systematic importance and differ from them fundamentally in many anatomical characters.

The head is short and conical, with apparently functionless facial whiskers and a moist elongate muzzle; the ear sometimes has a distinct pinna, but may be represented by a vertical slit only. The legs are short, but the feet, whose five toes are armed with large claws (curved on the forefeet), vary in structure according to habit. The tail, sometimes excessively long and prehensile and sometimes comparatively short, forms, with the hind legs, a kind of tripodal support. The anus and external genitalia are situated close together on an eminence formed mainly by the enlarged anal glands, and the anus is sunk in a depression into which the ducts of the glands open; both the penis and clitoris are quite small.

Pangolins range in Asia from north India and south China to Ceylon and Borneo and in Africa from Sierra Leone and Uganda to the Cape of Good Hope. There are several different kinds. Some are almost entirely arboreal, some purely terrestrial and others intermediate in habitat; all, however, are nocturnal and are able to swim a little. They feed mostly on termites, ripping open the nests of these insects with the strong claws of the forefeet. Their means of defense are emission of a repulsive odour from the large anal glands and rolling into a compact ball with the hard, often sharp, erected scales presented to the enemy and the soft-skinned hairy underside protected from injury.

There are several fairly distinct types, all usually referred to genus *Manis* and to the family Manidae, but there is some dispute about the scientific names. In the Asian pangolins the hinder end of the breastbone is shaped like the blade of a spade, having a convex posterior edge and two forwardly directed spinous angles. To this group belong the northern Indian and Chinese eared pangolin, the Indian and Ceylonese thick-tailed pangolin and the Javanese and Bornean pangolin, all of which differ in many external characters.

In the African pangolins the end of the breastbone is prolonged into two rods running back to the posterior ribs. There are two groups differing in habitat and correlated structural characters: the terrestrial, including the so-called giant pangolin, with the feet and tail adapted for ground life; and the arboreal containing the small west African pangolins, which differ from all other pangolins in being exclusively adapted to life in the trees, the tails being exceedingly long and prehensile, and the feet with only four functional toes, the upper side of the forefoot being without scales.

The earliest evidences of the Pholidota are the bones of a large pangolin, indistinguishable from those of the African giant pangolin, found in a cave in Madras, India. These remains date to the Pleistocene, beginning about 1,000,000 years ago.

See also PANGOLIN.

PHONEMATICS: *see* LINGUISTICS; PHONETICS.

PHONETICS is the study of speech sounds, their physiological production and acoustic qualities. It deals with configurations of the vocal tract used to produce speech sounds, the resulting acoustic patterns and the manner of combining sounds so as to make syllables, words and sentences. On another level it compares the speech sounds of different languages.

Phonetics, since it is part of the analysis of the phenomenon of human language and speech behaviour, contributes to the fields of anthropology, linguistics, psychology, sociology and related fields. Furthermore it has several practical objects: (1) to help in learning to pronounce foreign languages; (2) to contribute to speech therapy; (3) to record previously unwritten languages and to develop writing systems for them; (4) to develop more efficient electrical and electronic speech transmission systems (speech compression).

History.—Although phonetics as an independent field of study did not come into being until the 19th century, speculations regarding the nature and origin of human speech, usually connected with magical or religious practices, are found in ancient civilizations. The use of alphabetic or syllabic notation, as opposed to pure ideographs, to record human speech shows an at least intuitive knowledge of speech units and their relationships. One of the earliest attempts at a systematic description and classification of speech sounds was that of the Sanskrit grammarians, whose work came to its climax with Panini (4th century B.C.). From the classical era until the end of the 17th century, however, more emphasis was placed on the process of phonation rather than on an explicit analysis of speech units. Such descriptions can be found among the works of Hippocrates, Aristotle, Galen and, later, Leonardo da Vinci. Near the end of the 18th century considerable interest was shown in speech synthesis. In 1791 Wolfgang von Kempelen invented a machine which could produce speechlike sounds.

During the 19th century a number of recording devices, such as the kymograph, became available for the quantitative measure of speech phenomena. These devices, along with the artificial palate and X-ray photography, gave impetus to the quantitative study of

the physiology of speech. Comparable studies in the acoustic structure of speech were made available through Helmholtz resonators and phonographic devices. By 1881, when Eduard Sievers published his *Grundzüge der Phonetik*, phonetics had become an independent discipline. While the quantitative aspects of speech developed into experimental or instrumental phonetics under the influence of the abbé Jean Pierre Rousselot, another group of phoneticians became preoccupied with the classification of speech sounds and the creation of a notation system for recording speech in a written form. Leaders among this group were Paul Passy, Henry Sweet and Daniel Jones, all of them prominent in the sponsorship of the International Phonetic association which was inaugurated in France in 1886. The association soon drew up the International Phonetic Alphabet, which was designed to be applicable to all languages and which has become not only the most widely used phonetic alphabet but also the basis for many succeeding systems.

Jan Baudouin de Courtenay (1845–1929) is credited as being the first to insist on the distinction between the speech sound and the phoneme, although Henry Sweet (1845–1912) also was aware of the necessity to make this distinction. With the formation of the Cercle Linguistique de Prague in 1926, led by V. Mathesius, N. S. Trubetskoi, Roman Jakobson and S. Karcewski, new impetus was given to the development of phonemics and phonemic theory as distinct from phonetics.

After World War II, improvements in recording devices made available such instruments as the sound spectrograph, which permitted the analysis of speech sounds in great detail, and brought the acoustic study of speech sounds into the foreground. The interest in speech phenomena on the part of communication engineers and others outside the field of phonetics gave rise to an unprecedented study of all aspects of human speech.

Phonetic Analysis.—Speech sounds are recorded and analyzed in two general ways, either by ear or by machine. In the former method, the phonetician listens to a person speaking and writes what he hears in the symbols of a phonetic transcription system, recording in as detailed a manner as he can or as suits his purpose. In the latter method, speech is recorded with an instrument such as the oscilloscope, kymograph, spectrograph or X-ray camera. This usually transforms the speech behaviour into a visual form which can then be measured, and various samples of speech can be compared. In either case, when the object of the analysis is to describe the speech sounds of a given language, the nature and mode of formation of every speech sound of the language must be ascertained with the greatest possible accuracy; long passages of the language must then be transcribed phonetically as accurately as possible with the object of finding out how the sounds may be grouped into distinctive sounds, or phonemes. The usage of the particular language as regards the duration of sounds, the stress of syllables and the intonation (pitch, musical accent) of words and sentences must be examined in detail. To obtain the best results, investigations must be made by both methods.

Analysis by ear can be carried out only by an observer who is a trained phonetician; *i.e.*, a person who has been trained to distinguish and recognize minute shades of sound and recognize and imitate a number of foreign sounds and sound combinations. He must have as a collaborator a native speaker of the language to be analyzed. The phonetician asks the native speaker to repeat words and phrases of his language a number of times. He may find these words and phrases to be composed of sounds already known to him. If so (and if the language does not present special difficulties in the matter of length, stress or intonation), he will at once be able to repeat them to the native's satisfaction. If the native is not satisfied, it means that the word or phrase contains one or more unfamiliar sounds or that the language contains some unusual features of length, stress or intonation. To acquire the

TABLE I.—*The International Phonetic Alphabet**

		Bilabial	Labio-dental	Dental and alveolar	Retroflex	Palato-alveolar	Alveolo-palatal	Palatal	Velar	Uvular	Pharyngal	Glottal
Consonants	Plosive	p b		t d	ʈ ɖ			c ɟ	k g	q ɢ		ʔ

	Flapped			ɾ	ɽ					ʀ		
	Fricative	ɸ β	f v	θ ð | s z | ɹ	ʂ ʐ	ʃ ʒ	ɕ ʑ	ç j	x ɣ	χ ʁ	ħ ʕ	h ɦ
	Frictionless Continuants and Semivowels	w | ɥ	ʋ	ɹ				j (ɥ)	(w)	ʁ		
Vowels		Rounded						Front Central Back				
	Close	(y ʉ u)						i y ɨ ʉ ɯ u				
	Half-close	(ø o)						e ø ɘ ɵ ɤ o				
	Half-open	(œ ɔ)						ɛ œ ɜ ɞ ʌ ɔ				
	Open	(ɒ)						æ ɐ a ɑ ɒ				

*Secondary articulations are shown by symbols in parentheses.

OTHER SOUNDS.—Palatalized consonants: ʇ, ɖ, etc. Velarized or pharyngalized consonants: ɬ, ɗ, ƶ, etc. Ejective consonants (plosives with simultaneous glottal stop): p', t', etc. Implosive voiced consonants: ɓ, ɗ, etc. ɾ fricative trill. ʊ, ǫ (labialized θ, ð, or s, z). ʕ, ʒ (labialized ʃ, ʒ). ɪ, ʗ, ɔ (clicks, Zulu *c*, *q*, *x*). l (a sound between ɾ and l). ʍ (voiceless w). ɪ, ʏ, ʊ (lowered varieties of i, y, u). ɜ (a variety of ə). ɵ (a vowel between ø and o).

Affricates are normally represented by groups of two consonants (ts, tʃ, dʒ, etc.), but, when necessary, ligatures are used (ʦ, ʧ, ʤ, etc.), or the marks ‿ or ⁀ (t‿s or t⁀s, etc.). c, ɟ may occasionally be used in place of tʃ, dʒ. Aspirated plosives: ph, th, etc.

LENGTH, STRESS, PITCH.—ː (full length). ˑ (half length). ˈ (stress, placed at beginning of the stressed syllable). ˌ (secondary stress). ˉ (high level pitch); ˍ (low level); ˊ (high rising); ˏ (low rising); ˋ (high falling); ˎ (low falling); ˆ (rise-fall); ˇ (fall-rise).

MODIFIERS.—˜ nasality. ˭ breath (l̥ = breathed l). ˬ voice (s̬ = z). ʻ slight aspiration following p, t, etc. ˈ specially close vowel (e̝ = a very close e). ˌ specially open vowel (e̞ = a rather open e). ̫ labialization (n̫ = labialized n). ̪ dental articulation (t̪ = dental t). ʲ palatalization (ż = ʒ). ˠ tongue slightly raised. ˞ tongue slightly lowered. ˃ lips more rounded. ˂ lips more spread. Central vowels ɨ (= i̽), ʉ (= u̽), ɘ (= e̽), ɵ (= o̽), ɜ, ɞ. ̩ (e.g. n̩) syllabic consonant. ̯ consonantal vowel. ʃ̡ variery of ʃ resembling s, etc.

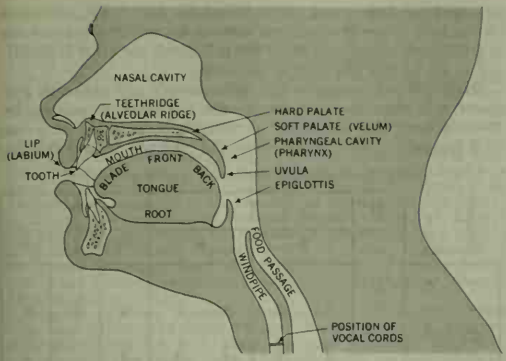

FIG. 1.—THE ORGANS OF SPEECH

correct pronunciation, the phonetician makes fine adjustments in the positions and movements of his own speech organs in repeating the words to the native speaker. He tries one variation and then another until he succeeds in pronouncing the word or phrase to the native's satisfaction. He then knows by his own muscular and tactile sensations what is the exact manner of formation of the unfamiliar sounds of the language.

Analysis of speech sounds by the acoustic method may be checked by experimental methods; *i.e.*, investigation by instruments. The positions of the tongue and velum (soft palate) and of the shapes assumed by the pharyngeal cavity may be more easily ascertained with the help of X-ray photography. Indications of tongue positions may also be found by the use of a special kind of artificial palate.

Phonetic Symbols.—In nearly every language the number of distinguishable sounds is greater than the number of letters in the Roman (Latin) alphabet. It is therefore impossible to represent most languages unambiguously by means of the ordinary Roman letters only. Any "romanic" phonetic system, therefore, whether designed as a current orthography or as a transcription for the use of language learners, must contain new letters to supplement those of the present Roman alphabet.

Classification of Speech Sounds.—Table I, showing the International Phonetic Alphabet (IPA), taken in conjunction with the chart of the organs of speech (fig. 1), shows the chief principles of sound classification. The meanings of most of the technical terms describing the various classes of sounds are self-evident. Attention may be called, however, to the following, which require some explanation: The back of the tongue is the part which lies normally opposite the soft palate; the front is the part which lies normally opposite the hard palate; the blade is the part which lies normally opposite the teethridge (upper gum, alveolars). Palatal consonants are those formed by the front of the tongue against the hard palate, such as the English sounds of *y* or the German *ch* in *ich*. Retroflex consonants are those made by the tip of the tongue against the hard palate, such as the Hindi sounds of ट ड. (*See* also VOICE; PRONUNCIATION.)

Intonation.—An important branch of phonetics is that which deals with intonation, or the rise and fall in the pitch of the voice. In the languages called tone languages (*e.g.*, Chinese and most Sudanic and Bantu languages) intonation is used to distinguish one word from another. Thus in Cantonese the syllable *fan* said with a high falling tone means "divide"; said with five other tones it means "powder," "sleep," "burn," "courageous" and "duty," respectively. In the Sechuana language (Bantu) of South Africa, *metse* said with a mid-level tone on each syllable means "villages," but with a mid-level tone on the first syllable and a high-level tone on the second it means "water."

In languages which are not tone languages intonation affects the meaning of whole sentences, but it is not an integral part of any word. Intonation gives expression to sentences; it conveys shades of meaning which cannot conveniently be expressed by other means. Thus in English the two meanings of *I beg your pardon* ("I am sorry" and "What did you say?") are distinguished by intonation. It is not practicable to mark this kind of intonation in orthography, though slight indications of it may be given by the use of punctuation marks or italics.

Phonetic Description.—The sounds of speech are usually described either in articulatory or in acoustic terms.

Articulatory descriptions are based on the parts of the vocal tract which are used in forming a given sound (*see* fig. 1). For instance, vowel sounds can be classified according to several positions of the articulators such as the tongue, the lips and the degree of mouth opening. Fig. 2 shows the tongue positions for several vowels. Fig. 2 (left) shows a series of front vowels, so-called because the tongue is bunched forward in the mouth as opposed to the back vowels in fig. 2 (right) in which the tongue is bunched toward the back of the mouth. In fig. 2 (left) the letter [i], which is the phonetic symbol for the "ee" sound in "meet," is the highest of the front vowels, and [a] as in "cat" is the lowest of the front vowels, since the tongue is not so high toward the roof of the mouth. In fig. 2 (right), [u] as in "who" and [ɑ] as in "father" are the highest and lowest back vowels, respectively.

In some languages, such as Russian and Spanish, it is more efficient to describe the vowel sounds in terms of lip rounding and mouth opening. In such languages [i] is described as an unrounded close vowel since the mouth opening is slight and the lips are not rounded or pursed as they are in [u], which is a close rounded vowel. These two vowels differ from the vowel [ɑ] which is open and has no significant rounding or unrounding. (It is rather difficult to drop the jaw and purse the lips at the same time!) Nasal vowels are produced by dropping the velum (soft palate) so that the nasal passage is open. (In the case of nasal vowels, the air does not usually pass through the nose, which is used only as an additional resonator for the sound.)

Consonantal sounds are described in terms of point of articulation. For instance, [p] is called a bilabial because both lips are brought together to produce the sound, as opposed to the [t], which is called a dental sound because the tip of the tongue is at or near the upper front teeth. Both of these differ from [k], which is articulated with the back part of the tongue somewhere in the region of the velum; hence it is called a velar sound. Consonants are also described in terms of the activity of the air stream in the mouth and the activity of the vocal cords. When the vocal cords are vibrating the sound is said to be a voiced sound; otherwise it is voiceless. When the air stream must pass through a narrow opening, as in [f] or [s], the sound is called a fricative. The air stream is continuous in the fricatives but interrupted in the plosives or stops ([p], [t], [k]).

In the case of the nasal consonants such as [m] and [n], the velum is dropped, as it is for nasal vowels, and part of the air stream passes through the nose. Finer degrees of articulation are shown in the IPA chart (Table I).

In describing the acoustic qualities of speech sounds it is convenient to consider their source and transfer functions. The former refers to the kind of excitation involved; *i.e.*, whether the sound is periodic or random (turbulent). When the vocal cords vibrate they produce a complex periodic wave form composed of

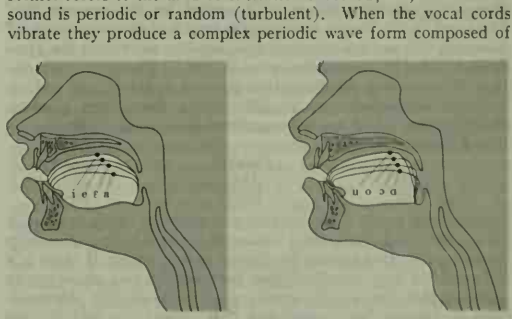

FIG. 2.—TONGUE POSITIONS OF (LEFT) THE FRONT CARDINAL VOWELS AND (RIGHT) THE BACK CARDINAL VOWELS

a fundamental and its harmonics. On spectrograms (narrow band) such a wave form appears as a series of horizontal lines, longer or shorter depending on the duration of the sound. When the air stream is caused to pass through a narrow constriction, as in the fricatives (*e.g.*, [s], [f]), the spectrogram shows a gray smear covering the entire frequency range.

The various cavities in the vocal tract act as resonators which either reinforce or cancel out some frequencies or frequency regions of the original excitation function. Hence it is convenient to consider the source function to be the substance of the sound and the transfer or resonance function as its form. In vowels, for instance, the source is periodic and the resonators cancel out certain groups of harmonics and reinforce others. A typical sound spectrogram of a vowel resembles music notation paper, a series of staves composed of lines, with blank spaces between. Such a staff of harmonics is called a formant or a bar, and indicates a resonance region.

Except under very special circumstances, these formants are independent of the pitch or fundamental frequency at which the vocal cords are vibrating, since they are given their form by the shape of the resonating cavities in the vocal tract. Since the vocal tract assumes a different shape for each of the vowels, as explained above, the resonances or formant frequency regions of each vowel differ from those of other vowels.

It has been found that the vowels of most languages can be differentiated by describing the lowest two (or three) formants, which occur between 250 and 3,000 cycles per second (c.p.s.). Thus the two significant formants of the [i] sound occur at the lower and higher limits of this region, those of the [u] both at the lower end of the region and those of [a] in the centre of the region.

When the source function is not periodic, the resonators also reinforce certain frequency regions and cancel out others, but these regions are usually called resonance regions rather than formants. Thus a spectrogram of [s] will show a gray smear in a high-frequency region (around 6,000 c.p.s.) and [f] a weak smear at a very-low-frequency region. The stops differ from the fricatives in the way they begin. The stops begin abruptly and have a short spike-like appearance on spectrograms, whereas the fricatives begin smoothly and are longer in duration.

The Phoneme.—The only significant difference between the English words "ban" [bæn] and "man" [mæn] is in the first sound. While both are labial sounds, one is a nasal and the other is a stop. When a word can be transformed into another word by such a change, the two sounds are said to be distinctive or phonemic. They are, or they represent, two different phonemes. Phonemics (an alternate term, phonematics, is preferred by some linguistic authorities) is the analysis of the distinctive sounds or phonemes of a language.

Phonemic distinctions differ from one language to another, hence each language has its own set of phonemes or distinctive sounds. For instance, in Czech there is a difference between long and short vowels: *náraz* [na:ras], "shock"; *naráz* [nara:s], "at once." This distinction does not hold for most varieties of English, although there is a phonetic difference in vowel length between "hit" [hɪt] and "hid" [hɪ:d]; changing the length of the vowel in "hit," however, will not transform it into another word, and the same holds true for shortening the vowel in "hid." Phonemic transcriptions indicate only the distinctive qualities of the sounds and are enclosed in slanted lines to differentiate them from phonetic transcriptions, which are not committed to indicating only distinctive differences:

	Phonetic	*Phonemic*
"hit"	[hɪt]	/hɪt/
"hid"	[hɪ:d]	/hɪd/

When two words differ by only one phoneme, such as English "bat" /bæt/ and "sat" /sæt/, the words are said to be a minimally distinct pair. In a minimally distinct pair of words, if there is a difference of only one distinction between the two phonemes in question, then the two phonemes are minimally distinct phonemes. Thus in English "pat" /pæt/ and "bat" /bæt/, /p/ and /b/ are both stops, both are bilabial and the only difference is that /p/ is unvoiced (or tense) and /b/ is voiced (or lax). The phonemes /b/ and /s/ in the previous example are not minimal because one is a fricative, the other a stop; one is bilabial, the other is dental; one is voiced and the other is unvoiced.

Distinctive Features.—For both phonetic and phonemic purposes it is often necessary to describe the relations existing between sounds, the "structure" of relations between the phonemes of a language. Most phoneticians and linguists achieve this end by using the phonetic classifications, either articulatory or acoustic (or both), such as those outlined above. A system for describing these distinctive features in binary terms was developed by Roman Jakobson and his collaborators shortly after World War II. This system describes the phonemes of a language in terms of the presence or absence of a small number of distinctive features based on articulatory or acoustic terms.

Source: L. G. Jones, "English Consonantal Distribution," in *For Roman Jakobson*, p. 246 (Mouton, The Hague, 1956).

Table II shows such an analysis based on one variety of American English. The plus (+) indicates the presence of that feature, the minus (−) its absence, the zero (0) its irrelevance. The (±) sign usually is used only where the feature can be described in terms of a scale of such values as high, mid or low, and is avoided wherever possible.

This type of classification, utilizing as it does the binary notation system of the mathematical theory of communication, can be used to great advantage wherever phonetics and phonemics play a role, from the learning of foreign languages to the development of more efficient electronic speech compression systems.

PHONOGRAPH, an instrument for reproducing sound by transmitting to the air (directly or indirectly) the mechanical vibrations of a stylus in contact with a sinuous groove in a moving record. In a wider sense a phonograph is any instrument for reproducing recorded sound. In this expanded view the record may be mechanically, optically (photographically) or magnetically recorded and reproduced as sound by appropriate apparatus.

Information on related phases of sound reproduction can be found in the articles HIGH-FIDELITY SOUND SYSTEMS; LOUDSPEAKER; and TAPE RECORDING, MAGNETIC. This article consists of the following parts:

I. HISTORY

A prototype of the phonograph appeared in 1857 when Leon Scott constructed a device he called the Phonautograph, which recorded, as a wavy line on the smoked surface of a rotating cylinder, the movements of a diaphragm or other vibrating body. The first record of vibrations which could be played back to reproduce sounds was invented by Thomas A. Edison in 1877. The record was in the form of indentations pressed into a sheet of tin foil by the vibrating recording stylus, which was attached to a diaphragm. The tin foil was wrapped around a cylinder that rotated as the sounds were being recorded. A thread on the shaft moved the cylinder axially as it rotated, so that the record groove was helical. A small helical groove having the same pitch was cut in the surface of the cylinder, and the recording diaphragm and stylus were positioned to bring the groove directly under the slightly rounded point of the stylus, thus making it easier to produce the indentations in the tin foil. The sound waves were recorded as variations in the depth of the groove. For reproduction the groove was again run under the stylus tip, with only enough pressure to maintain contact with the groove bottom. The term "embossing" has been widely used to designate the method of recording in which the groove is impressed in a yielding material by a rounded point.

Edison took steps toward the exploitation of his invention, which he called the phonograph, but he was soon diverted to the development of the incandescent lamp and electric power systems. Several years after the first flare of publicity which followed Edison's demonstrations, Alexander Graham Bell became interested in the phonograph, and with two associates, Chichester A. Bell and Charles Sumner Tainter, began experiments in Bell's "Volta" laboratory in Washington, D.C. They had best results with an arrangement much like Edison's except that their machine cut or engraved the groove in a cylindrical surface of wax with a sharp tool carried by the vibrating diaphragm. This gave much better sound reproduction than had been possible with Edison's indented tin foil. In 1885 C. A. Bell and Tainter applied for a U.S. patent on this principle and other features of their developments, and in 1887 they organized a company to manufacture and sell Graphophones, as they called their machines. Edison returned to his experiments with the phonograph, and he too became convinced of the superiority of the engraved wax groove.

Various promotional and organizational activities took place in the next few years, the most important results of which were that the Columbia Phonograph Co. became the manufacturing and selling organization for the Bell and Tainter developments, and rights under both the Edison and the Bell and Tainter patents became available to both the Columbia and Edison companies.

1. Disc Recording.—Another inventor, German-born Émile Berliner, was responsible for a radical departure in sound recording. The initial step in Berliner's recording operation resembled that of Scott's Phonautograph, except that Berliner's mechanism traced its wavy line as a spiral on a flat disc, instead of as a helix on a cylindrical surface. The disc was of zinc, coated with a thin layer of fatty substance which protected it from the action of acid except where the scribe had traced its line. An acid bath then left a groove, the width and depth of which could be controlled by the duration and strength of the acid treatment. Berliner thus obtained a record which could be played by means of an appropriately designed reproducing mechanism.

However, he did not contemplate using this etched master as the record to be played; rather, a negative was made from the master by electroforming, and the negative then was used to mold records in some thermoplastic material, a procedure that subsequently became standard. Berliner first proposed using vulcanite or hard rubber as the molding material, but he later found a company that could mold records for him in a material much like that which later became common for all records. Berliner's records were far harder and more durable than the waxes of which the cylinders were being made. The harder material, plus somewhat greater amplitudes due to the fact that the recording stylus did not have to work against any cutting resistance, made somewhat greater volume possible in the reproduced sound.

Of still greater importance to the success of Berliner's discs, however, were the ease of molding from a flat surface and the fact that he could make his grooves deep enough to guide the

reproducing stylus across the record without the need for an auxiliary feed screw. It was to the latter feature that the most important of Berliner's patent claims were directed.

Small-scale manufacturing of the Gramophone, as Berliner called his machine, was started in 1894. The Gramophones were much simpler than the cylinder machines of Edison and Columbia, and could be sold relatively cheaply, while records for them could be made at much lower cost. But driving the record by means of a hand crank was unsatisfactory for anything but demonstrating a principle. Berliner recognized the need for a clockwork drive and controlled speed. He sought outside help, and the problem was eventually brought to Eldridge R. Johnson, who operated a small machine shop in Camden, N.J. Johnson soon worked out a practical design for a spring-driven motor with a friction governor, and in a short time (1896) was building for the Berliner Gramophone Co. not only the spring motors but all the mechanical parts of the Gramophones. Besides developing the spring motor, Johnson made various improvements in the Gramophone, including a better "sound box," the principal features of which were retained with little change throughout most of the history of the acoustic phonograph.

Johnson's experiments soon convinced him that the noisiness of the Gramophone records arose from the roughness of the etched surfaces, and he began to study the possibilities of cutting the groove in wax as Bell and Tainter had done; however, instead of recording the vibrations as variations in depth of the groove (commonly called vertical or hill-and-dale recording), he followed Berliner's practice of recording them as sidewise deflections of a groove of uniform depth (commonly called lateral recording). Johnson mastered the techniques of rendering the wax surface conductive by dusting with graphite and then electroplating, thereby producing a "negative" of the grooved wax. This negative, built up in the plating process to sufficient thickness for needed strength, could then be used to press records in thermoplastic material. The records so made were much clearer and less noisy than those produced by Berliner's process.

For several years the sale of Gramophones and records grew and Berliner prospered, but in 1900 his one sales outlet stopped ordering, and then a court injunction was obtained by competitors (based on alleged infringement of a detail patent) forbidding his company to make or sell Gramophones. Johnson had an enlarged factory and a large inventory of machines. He decided to do his own selling. He started with an advertising campaign featuring greatly improved records produced by a newly developed process and offering a free sample. The business grew and prospered.

In addition to his own technical contributions Johnson now had a going business to offer in exchange for rights under the basic Berliner patents. In Oct. 1901 a new company was formed, the Victor Talking Machine Co., the stock of which went partly to Johnson and partly to Berliner, with the controlling interest in Johnson's hands.

A serious threat to the Victor company arose shortly after its formation, when the Columbia company acquired a patent describing and claiming the process of recording by cutting a laterally varying groove of constant depth in wax, exactly as Johnson was doing. The Columbia company was just beginning to make disc machines, but in so doing it was sure to fall afoul of Berliner's patents. Rather than engage in costly litigation the Victor and Columbia companies arranged for cross-licensing. Thenceforward, competition was in terms of such factors as costs, merits of machines, prestige and quality and popularity of available records.

2. European Developments.—The beginnings of the phonograph business in Europe were limited largely to the activities of sales agents from the already established American companies. Demonstrations of Edison's tin-foil machine were given in 1878 in England and Germany, where they created much interest but little else. A decade later Edison made a serious effort to extend his beginning business by demonstrating his wax cylinder system for many distinguished persons and making recordings of the voices of celebrities. The prices of machines imported from the U.S. were too high for any considerable sales for private use, but, as in the United States, many people were willing to pay a small fee to satisfy their curiosity and hear a machine talk.

As an attraction for their tavern, two Frenchmen, Charles and Émile Pathé, procured a phonograph from England. But when customers showed more interest in the possibility of buying a phonograph than in the other Pathé business, the brothers decided to start making phonographs. They started with a small shop and by 1894 were doing a thriving business, making machines and wax blanks. They were also active in recording, using mechanical methods of duplicating the records, and by 1899 had a large list of available cylinders, principally of popular French singers.

In Italy there was no large market for machines, but the music-loving public would pay at some public installations to hear their favourite operatic songs.

Aside from a short-lived venture of making Gramophones in their simplest (hand-cranked) forms, started in 1889 by a German toymaker, there was little commercial phonograph activity in Europe, except that of the Pathé brothers, until the arrival of emissaries from the then-prospering Berliner group: William Barry Owen in 1897 to establish a branch in England, and Joseph Sanders in 1898 to help Émile Berliner's brother start a record pressing plant in Hanover, Ger. By this time the quality of reproduction had reached a point that made the Gramophone of interest as a source of home entertainment and that induced well-known artists to permit their voices to be recorded. Owen eventually interested certain British investors, and the Gramophone company was organized there in 1898; it imported parts from the U.S. and assembled Gramophones in England. Records, at least at first, were processed and pressed at the Hanover plant. As soon as machines and

records became available, extensive advertising was begun, and in the autumn of 1898 sales reached the full capacity of the manufacturing facilities. Owen opened branches for Gramophone sales and recording activities in Berlin and in Russia and Austria, and finally in France and Spain. It was in Russia in 1900 that red labels were first used to distinguish recordings of celebrated artists. For these discs the size was increased from seven to ten inches. In 1899 Owen purchased for the Gramophone company the original painting of a dog listening to a phonograph, to which the name "His Master's Voice" was given. This was soon used as a trademark by the Victor company, and about a decade later also by the Gramophone company, whose records were designated by the initials "H.M.V."

Recording the lateral-cut gramophone discs in wax began in Europe as well as in the U.S. in 1900 but did not entirely supersede the etching system for a year or so.

3. Technical Developments in Acoustic Recording.—Aside from the great growth in the phonograph business and refinements from time to time in recording equipment and techniques, the history of the acoustic phonograph was marked by the following developments:

Methods of molding cylinder records of a relatively hard thermoplastic were introduced by the Edison and Columbia companies in 1901. Since these were announced as "gold molded," it is presumable that gold sputtering was used to give an electrical conducting surface to the wax original.

The Odeon company was formed in Berlin in 1903. The following year it introduced discs with recordings on both sides. Columbia began issuing double-sided records in 1908. Pathé began making hill-and-dale cut discs in 1906 and in 1908 offered 11-in. double-sided discs.

In 1908 Edison brought out cylinders of a new material which he called Amberol, which was harder than the materials previously used. By increasing the number of grooves per inch from 100 to 200 he could offer four minutes of playing time. In 1912 Edison introduced a further improvement in material; he called the new material, which was more resistant to abrasion, Blue Amberol. Roland Gelatt noted that the Blue Amberols were relatively noiseless and, when played with an Edison diamond reproducer, produced better results than any other type of music reproducer then available. In 1913 Edison began making discs and a phonograph to play them. However, he continued to make cylinders for owners of cylinder machines until his company ceased operations in 1929.

The advent of radio broadcasting in the early 1920s brought severe depression to the phonograph industry. The Columbia company went into receivership in 1923; the competition of the fast-growing radio industry did not seriously affect the Victor company until 1925. The introduction of electrical recording (by both Columbia and Victor), improved phonographs and combination radio receivers and phonographs soon brought recovery. The British Columbia company had fared much better than the U.S. company (now unaffiliated), and its president, Louis Sterling, bought controlling interest in the American company and took licences for both companies to use the new developments.

The Victor Talking Machine Co. was purchased by Radio Corporation of America in 1929. Its plant at Camden, N.J., became the production centre for radio equipment as well as phonographs and records.

4. Horns.—The performance of an acoustic phonograph is greatly affected by the size and shape of the horn; and while there was little in the way of technical study during the era of the acoustic phonograph, there was some progress toward better horns. Ear trumpets and megaphones had long been familiar, and the developers of phonographs were quick to take advantage of what horns could do for their machines. The horns assumed various shapes according to the ideas of those who made them. The easiest horn to construct is of simple conical shape, but after about 1920 the exponential horn was the nearly universal choice of engineers. A theoretical analysis of its characteristics was published by A. G. Webster in 1919, and the subject was further elucidated by C. R. Hanna and J. Slepian in 1924.

An exponential horn is one whose cross-sectional area doubles with each increase of x inches in distance along the axis from the small end; or, if it is a round horn, the diameter doubles with each increase of $2x$ in axial distance. A small value of x therefore yields a horn of rapid flare, while a large value yields a slowly expanding horn. Every exponential horn has a critical frequency, known as its cutoff; below this frequency the horn is of practically no use, while for higher frequencies it will reproduce very effectively. The cutoff frequency is that at which the wave length is approximately $20x$; hence, to extend the range of response to lower frequencies, x must be made large. To avoid horn resonance, Hanna and Slepian recommended that the expansion be carried to the point at which the surface (of a horn of circular cross section) makes an angle of 45° with the axis. This results in a large bell or final opening.

From the time of the very first phonographs it was customary to funnel the total air displaced by a diaphragm into a horn opening of considerably smaller diameter. This results in greater loading of the diaphragm, reducing its tendency to resonate (*i.e.*, damping it) and deriving from it increased sound power. The volume of air within the sound box must be small so that appreciable compression will not take the place of air flow.

Horns can be bent or "folded" to conserve space without too seriously impeding their performance, provided the difference between the shortest and longest paths around the bend is not over about one-third the shortest wave length to be transmitted.

Comparing a conical horn with an exponential horn of the same length and initial and final openings, the cone expands much more rapidly at its small end and much more slowly near the large end. The result is that the conical horn gives some multiplication of air flow at frequencies well below the cutoff frequency of the exponential horn, and the output climbs gradually through a long range of frequency, without ever quite overtaking that of the exponential horn above its cutoff.

The horns of the early phonographs were in some cases frustums of simple cones, but more frequently they ended in a rapidly flaring bell, like a trumpet. In some cases the angle between side and axis increased toward the large end, giving a shape between that of a cone and an exponential horn. However, early horns were relatively small and were not designed to avoid resonances due to reflections at the bell. Some of the resonant points may have been regarded as desirable for increasing sensitivity. The feeble response at low frequencies was of less consequence, since there was little of low frequency on the records. Recording equipment was usually provided with larger horns, often of simple conical shape.

As experience accumulated, the sizes of horns increased, at least on the better machines. In 1906 the Victor company marketed a machine with the horn built into the cabinet. This facilitated increasing the horn size and also made it desirable to keep down the size of the middle part of the horn, thus favouring a shape somewhat closer to the exponential. The slight taper of the swinging pickup arm, which constituted the first part of the horn, increased the general resemblance to the exponential shape. In later models with larger cabinets, larger and still better-shaped horns were employed. However, it was not until the introduction of the Orthophonic design in 1925 that a definitely planned exponential expansion was followed, with considerable increase in length and with an end opening occupying practically the whole front of a large cabinet.

II. ELECTRICAL RECORDING AND REPRODUCTION

Prior to 1925 the phonograph had been developed almost wholly on an empirical or "cut-and-try" basis, with little theoretical analysis and all decisions based on listening tests. Recording was looked upon as an art, and rightly so, for the judgments of an experienced recording engineer as to balance and choice of selections were of utmost importance. Certain voices and instruments recorded well while others did not, and early recognition of poor qualities could often forestall wasted recording sessions. Details of recording equipment and practices were often treated as trade secrets. To the old-line phonograph organizations, the rapidly

developing and expanding radio and electronics industries seemed almost unrelated to their own, and few of them sought any help from electronics technicians.

The great difficulty in all direct recording lay in the extremely limited amount of acoustical power which could be collected and applied to actuate the diaphragms of the record-cutting devices. Only in the electronics field was there such a thing as an amplifier capable of multiplying sound power a thousandfold and more, with almost no loss of quality. The initiative in the development of electrical recording was taken by the Western Electric Co. Some work looking toward phonograph applications had been started as early as 1915, interrupted by the war, and then resumed soon afterward under the direction of J. P. Maxfield. The men who took part had extensive experience not only in amplifier applications but in the many electrical and mechanical problems encountered in telephone apparatus and transmission. Much use had been made of electrical-mechanical analogies which helped make experience in the electrical field applicable to mechanical problems and vice versa.

1. Theoretical Aspects.—In the development of electrical recording and reproducing apparatus an important principle of design of vibrational apparatus was introduced. The essential moving parts of either a recorder or reproducer have a certain amount of mass. Forces to actuate these masses must be produced magnetically in the case of the recorder or by the action of the record on the needle tip in the case of the reproducer. It is desirable to minimize the required forces. It happens that it is not necessary for all of the moving elements of either device to be combined into a single mass. In the recorder the armature of the electromagnetic motor can be separate from the stylus bar and stylus. In the reproducer the needle with its clamp and the lever which connects it to the diaphragm constitute one part; the diaphragm constitutes the other principal mass. If a phase difference can be permitted between the motions of the two related parts, the maximum force that must be applied to the needle to vibrate these masses can be practically halved. The introduction of an elastic connection or "compliance" permits this phase difference. In the recording cutter the torsional flexibility of a short shaft, between the motor armature and the bar carrying the stylus, offers the compliance, and there is another such flexible shaft between the stylus bar and a disk to which the mechanical resistance device is attached. The moment of inertia of each mass element, and the flexibility of each shaft, must be closely adjusted to predetermined values, and the structure of alternate masses and compliances (which is the mechanical equivalent of an electrical low-pass filter) must be terminated by a true mechanical resistance of correct value; otherwise there will be irregularities in its response. A pure mechanical resistance is not easy to provide.

Some recording heads employed oil for viscous damping; others used special solid materials. In the case of the reproducing device employed in the Orthophonic Victrola, the compliance was provided by a springy "spider" through which the lever actuated the diaphragm, and the required mechanical resistance was obtained by the reaction of the air in the "sound box" and horn throat on the diaphragm. With appropriate proportioning of the sound box volume and the relative areas of horn throat and diaphragm, and with a sufficiently slowly expanding horn, the energy was radiated as useful sound and the diaphragm worked against a substantially pure resistance. The Orthophonic design not only reduced the reaction of the needle on the record but, because of its higher efficiency in radiating the vibrations, gave greatly increased sound output.

While the input impedance of the recording device was practically pure resistance throughout most of the frequency range covered, the springs that centred the motor armature between the pole pieces added a stiffness reactance which predominated over resistance below about 300 cycles per second (c.p.s.). The resulting characteristic of the recording system (expressed as stylus movement for constant electrical input) was of constant amplitude up to 300 c.p.s., and of constant velocity from 300 to 5,000 c.p.s., the upper limit being determined by the cutoff of the mechanical filter previously discussed. Were the constant velocity range extended much lower, the amplitudes at the lowest frequencies would be excessive, necessitating wider groove spacings.

Since the sound level needed for satisfactory operation with a microphone and amplifiers was far lower than had been needed for direct recording, the introduction of electrical recording made it no longer necessary to group the players close together around the recording horns, nor to resort to instruments of special construction. Orchestras and choral groups could perform under conditions similar to those to which they were accustomed in concerts. It was not necessary to give preference to instruments of high acoustical power nor to singers with powerful voices.

Licences were taken by the Victor and Columbia companies to use the Western Electric recording system and equipment, and to build phonographs utilizing the principles and design features described above. The name Orthophonic Victrola was applied to the Victor machine. The horn in this model had considerably greater length (six feet) and final opening area (about eight square feet) than any in previous machines, the rate of expansion being slow enough to make the horn effective down to 115 c.p.s. To accommodate the length within the cabinet the passages were bent or folded several times. The improvements in records and phonographs were quickly recognized and resulted in great increases in sales.

2. Electrical Reproduction.—Although the sound quality of the Orthophonic machine (which was nonelectrical) was excellent, the advantages of electrical reproduction—ease of control, high amplification and simplification by combining the phonograph and radio receiver—made it inevitable that the electrical system would sooner or later supplant the mechanical. The electrical loudspeakers of the early 1920s left much to be desired, and the transition would scarcely have taken place when it did were it not for the advent of a greatly improved loud-speaker described in April 1925 by C. W. Rice and E. W. Kellogg of the General Electric Co. It was marketed by Radio Corporation of America (RCA) in 1925 as a separate loud-speaker for radio, known as the Radiola 104. It has frequently been called the "dynamic cone speaker." In addition to employing the dynamic or moving-coil drive and a conical paper diaphragm (about six inches in diameter), it had the following features which were equally important to the successful results: a very flexible suspension of the diaphragm (fundamental resonance about 60 c.p.s.); a baffle to prevent air circulation between the front and back of the diaphragm; and an amplifier of adequate power capacity to avoid overloading. Prior to this, the means most widely employed for actuating loud-speaker diaphragms depended on the varying pull of a polarized electromagnet on an iron armature. To maintain the armature at the proper spacing from the magnet poles, it had to be held by a stiff spring, and therefore the very flexible diaphragm mounting was not feasible with such "magnetic motors." The first electrical phonograph using the new loud-speaker was the Panatrope of the Brunswick Balke Collender Co., first demonstrated in the autumn of 1925; it employed an electromagnetic pickup. Outstanding in its sound quality was the abundant bass. Early in 1926 the Victor Talking Machine Co. brought out several models of electrical phonographs, some of which were combined phonographs and radio broadcast receivers. These used pickups of the same (General Electric) design as the Brunswick, but for a short period the loud-speaker given preference was one utilizing a large horn built into the cabinet like that of the Orthophonic, with an electrical unit employing a relatively small diaphragm, driven by a balanced armature "motor." Another electrical phonograph which achieved considerable popularity was the Majestic, similar in general principles to the Brunswick but differing in design details.

The baffle loud-speaker offered an important practical advantage for use in homes, because the space requirements were much less than needed for horns of adequate size to give good bass, but for theatre and auditorium applications the directivity of horns was important and space was not so restricted. Designs varied, but practically without exception the horns were exponential in expansion rate and after about 1926 the diaphragms were coil driven. The improved loud-speakers for auditoriums, with improved pickups for reproduction from discs, were applied in the motion-picture

field, and resulted in the rapid conversion from silent to sound motion pictures. The commercial realization of this change started in 1926, and the earliest commercially successful sound pictures made use of lateral disc records 16 in. in diameter operating at a turntable speed of 33⅓ r.p.m. and synchronized with the motion-picture film. (*See* also LOUD-SPEAKER.) (E. W. KE.)

3. Evolution of Fine-Groove Records.—A number of factors played a part in the evolution of fine-groove records. The demonstrations by H. C. Harrison and H. A. Frederick in 1931 of their new hill-and-dale acetate records showed what could be done in greatly reducing surface noise through use of refinements in record processing and a pickup with low vertical force and low mechanical impedance; the pickup permitted use of softer record material, free of any filler such as was used in the shellac records. The development of feedback recorders, the vertical recorder by L. Vieth and C. F. Wiebusch, and the lateral feedback recorder by G. R. Yenzen, also helped contribute to low distortion, extended range and smoother response obtainable with a feedback control that included the vibrating system.

But there were obstacles to change in the home phonograph field, obstacles that applied in much less degree to broadcast transcription service. The first magnetic pickups had rather high output, so their signals could be fed to the first audio stage of radio receivers without additional amplification. But they were also of high mechanical impedance (stiff needle mounting), the correction of which would reduce the output, and high mechanical impedance necessitated high vertical force. Cost-conscious designers were reluctant to put in more amplification. Because there were in existence, millions of records hard and tough enough to stand such forces, incentive to make a change was lacking. It was not until H. J. Hasbrouck's work on elimination of noise from the pickup and record that a pickup having truly low mechanical impedance was adopted. This permitted reducing the vertical force on the stylus to a few grams, but such small forces were insufficient to trip some record changers; consequently, full advantage could not be taken of the new pickups without improvements in record changers.

The reduction in necessary vertical force was so great as to make it feasible to use stylus tips of reduced radius, resting against the sloping sides of the groove instead of on the bottom; furthermore, this could be done while using records of clear vinylite, free from fillers. The advantages of using a finer stylus tip—in reduced tracing distortion, in finer groove pitch and in permitting some reduction in linear velocities—had been realized for a number of years but were especially convincingly shown in the analytical papers of F. V. Hunt, J. A. Pierce and W. D. Lewis, who also demonstrated a practical design for a low force, jewel-tipped pickup. They also showed the superior tracing possible with lateral-cut records, provided the spherical stylus tip maintained contact with the sloping side walls of the groove and cleared the bottom.

The dimensions of a record groove are determined by the lateral displacement of the groove resulting from the signal, or music, and by the dimensions of the reproducing stylus. It is evident that a reduction in either or both of these factors permits a reduction in the dimensions of the groove and thus makes possible a smaller record or a record having longer playing time. The use of less noisy record materials permits a reduction in the lateral displacement of the groove without reducing the signal-to-noise ratio. The use of pickups with a lower value of mechanical impedance permits the use of a smaller reproducing stylus. Experimental evidence proved that up to 300 grooves per radial inch and a reproducing stylus with a radius of 0.001 in. were practical.

The amount of distortion in the signal reproduced from the record groove increases as the stylus moves toward the centre of the disc—that is, as the relative circumference of the groove decreases and the relative speed of the groove past the stylus decreases. Therefore, the speed at which a disc record should rotate is related to the amount of recorded material it contains, and both speed and amount of material are governed by the circumference of the innermost groove that will give the maximum permissible distortion.

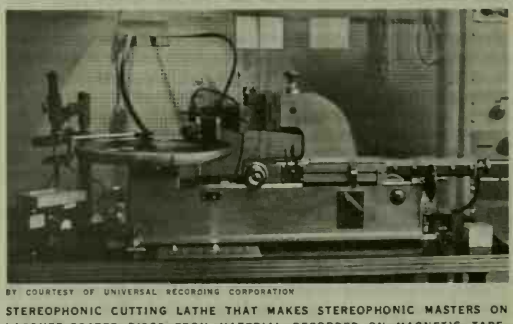
In addition, there is a definite relationship between the diameters of the outermost and innermost grooves that gives the maximum playing time per unit surface area. This relationship is such that maximum playing time for a disc of given size will be achieved if the diameter of the innermost recorded groove is one-half the diameter of the outermost groove; this relationship also is governed by the amount of permissible distortion in reproduction obtained from the innermost groove.

It is important to note that any major change in playing time calls for a change in speed of the record in order to achieve the least area or amount of record material, as the case may be. This assumes no change in the other factors, such as the radius of the reproducing stylus, the lateral displacement of the groove or the reproduced distortion at the innermost groove.

Modern disc records are designed with full knowledge of these principles. Other factors of a practical nature have resulted in some deviations from the purely theoretical considerations of disc record design. In 1948 both Columbia and RCA introduced fine-groove records of clear vinylite. The Columbia version was 12 in. in diameter, rotated at 33⅓ r.p.m. and had a maximum playing time of 30 minutes. The RCA version was seven inches in diameter, rotated at 45 r.p.m. and had a maximum playing time of eight minutes. After several months of testing the market, the change to fine-groove records became complete, with Columbia and RCA each making both versions.

The justification for these two records results from the wide difference in the playing time of "popular" and "classical" music. Each of the new records offered major improvements in cost, convenience and performance over the older 10- and 12-in. 78.26-r.p.m. records. (A. D. B.)

4. Stereophonic Phonograph Records.—Stereophonic phonograph records with two separate channels of information recorded in a single groove became a commercial reality in 1958, less than a year after the adopted system had been publicly demonstrated. A stereophonic system utilizes two or more independent channels, with separate microphones in recording and separate loud-speakers in reproduction, so arranged as to produce a sense of realism of recording hall acoustics and of location of the instruments of the orchestra with respect to directivity and depth. The effectiveness of stereophonic reproduction was demonstrated by the Bell Telephone laboratories in 1933 when the sound of an orchestra playing in Philadelphia was reproduced over loud-speakers located in Washington. The material was not recorded but was transmitted directly over telephone lines. Two-track stereophonic tape for the home became common in the 1950s, and Emory Cook produced some commercial stereophonic disc records, laterally recorded, in which the two channels of information were carried as separate inside and outside bands on the record; reproduction was through a forked arm carrying two pickups, one riding in each band.



BY COURTESY OF UNIVERSAL RECORDING CORPORATION

STEREOPHONIC CUTTING LATHE THAT MAKES STEREOPHONIC MASTERS ON LACQUER-COATED DISCS FROM MATERIAL RECORDED ON MAGNETIC TAPE. ARM ON LEFT IS FOR PLAYBACK

The system finally adopted as standard used a dual-channel feedback recorder and a single stylus with its axes of movement inclined at 45° to the record surface, the pickup being designed to produce two practically independent signals in accordance with the motion components along the two (90° displaced) axes. Since

the record groove is V-shaped and ordinarily has an included angle of 90°, the groove walls are 45° with respect to the record surface. Consequently, for the 45°–45° system the signal from one channel varies the position of one groove wall about a mean (no-signal condition) without changing the position of the other.

Operation at 45° provides a symmetrical arrangement that offers advantages both in design of recorders and reproducers and in quality of reproduction, since frequency response, distortion and other characteristics of the two channels are alike. In addition, good reproduction is possible over a single channel (monophonic) system since information from both stereophonic channels is contained in the resultant lateral modulation. However, due to the vertical modulation, monophonic pickups must have greater vertical compliance than normally required for lateral records. P. C. Goldmark recognized this problem in earlier work on stereophonic disc recording and proposed that the vertical modulation be dynamically held within limits that would not exceed the tracking capabilities of existing lateral reproducers. Such a record could be designated as "compatible" and could be reproduced either monophonically over phonograph systems designed for lateral-cut records or stereophonically over stereophonic systems. However, not wishing to risk possible reduction in quality, record manufacturers decided to follow the recommendation of the Record Industry Association of America and produce the two types of records, monophonic and stereophonic, separately. (H. E. R.)

III. RECORD MATERIALS AND PROCESSING

The early tin foil and other recording media ultimately were supplanted by materials of two general types: the wax disc (actually a heavy-metal soap with wax gel) intended for subsequent processing and duplication, and the instantaneous media intended mainly for playback directly from the embossed or engraved original record.

The necessary accuracy of the recorded groove can be judged by the requirements established for fine-groove records: that the bottom radius of the groove be less than 0.00025 in. and the width about 0.0025 in., giving a depth of about 0.00125 in. This is less than one-half the groove size of the 78-r.p.m. record.

In cutting or engraving the master record the stylus must be sharp and accurately ground so that the cut will be very clean. Lacquer-coated discs, usually on an aluminum base, were developed as an instantaneous recording medium, but because of the slightly rubbery nature of lacquer a smooth, low-noise groove was not obtained. The development of a burnishing facet on the stylus cutting edge resulted in quieter grooves but increased cross-modulation (echo) between adjacent grooves. The introduction of the heated cutting stylus about 1950 improved lacquer recording to the point where wax discs became practically obsolete for commercial master recordings.

1. Electroforming.—To make copies of the recording, dies must be made whose surface is a negative replica of the master record surface. Electroforming techniques which reproduce the surface to an accuracy of better than 0.000001 in. are utilized. In electroforming, the surface is made the cathode in an electrolyte solution containing the metal to be deposited. The neutralization (reduction) of the positive metal ions at the cathode surface forms a metal sheet whose thickness is proportional to the current and time.

Before this can be done, however, the master record surface must be made electrically conductive. Prior to 1938 wax recordings were made conductive by brushing graphite or bronze powder into the wax surface. In the 1930s Western Electric introduced gold sputtering, which was widely adopted by the major record manufacturers. With the improvements in lacquer discs and recording techniques, it was found that wet-silvering methods (*e.g.*, the chemical reduction of an ammoniacal silver solution such as that used for silvering mirrors) led to improved results. By the early 1950s, in view of the more stringent requirements of the unfilled-plastic records and particularly the fine-groove records, lacquer discs with wet-silvering metallizing had been universally adopted by major record manufacturers.

After separation from the recording, the electroformed metal master disc can be used in a plastic molding press to press records, and in cases where only up to 100 or so records are desired this usually is done. In the case of commercial records, many pressing masters, called stampers, may be needed. Therefore, it has been the practice to electroform a metal positive from the metal master. This positive, called a "mother" or mold, can be played as a record for quality approval and then used to generate a number of stampers by electroforming. By using a metal master to generate a number of molds and each mold to generate a number of stampers, it is possible to make many stampers, and thus thousands of records, from each recording.

2. Record Materials.—Commercially, records are molded from thermoplastic materials, which become soft and flow under pressure when heated but when cooled to room temperature become rigid. Shellac, a natural thermoplastic, was used in combination with a finely ground filler such as clay for many years, but after the early 1930s synthetic thermoplastic resins gradually replaced it. High-quality record compositions without filler were first used for transcription records for radio broadcast. With the introduction of the fine-grooved records, use of the higher-quality compound became necessary to reduce the noise caused by the filler particles. Of the synthetic materials, the vinyl plastics are most commonly used for records.

IV. PHONOGRAPHS AND RECORD CHANGERS

1. Stylus Shapes and Materials.—Except for the Edison hill-and-dale phonograph, which had a diamond reproducer stylus, most phonographs prior to 1935 required frequent changes of stylus or needle. Heavy pickups, weighing from 100 to 200 g. and bearing upon the small area of contact at the tip of the stylus, can exert pressures far in excess of the strength of record materials. Shellac-compounded mixtures used in records included a large proportion of abrasive filler, usually fine limestone and clay, which soon ground the tip to conform to the groove shape. In this way the contact area between stylus and groove was increased materially, thus decreasing the unit pressure so that record wear was reduced. When, between 1933 and 1935, attempts were made to use sapphire styli with electrical pickups weighing 50 to 150 g., record wear was found to be excessive, probably because the sapphire could not quickly be worn sufficiently to reduce the unit pressures at the stylus tip to a satisfactory level. It was not until the introduction in the late 1930s of pickups weighing less than 35 g. that sapphire and diamond styli became practical. The lighter pickups also permitted the use of unfilled-plastic record materials.

When comparatively large forces were necessary to extract the signal from the groove, the output was affected by the type of needle used. A short, stubby steel needle resulted in high output with good high-frequency response, but this also brought out the surface noise of the record. With a longer, thinner-shanked and more flexible needle, the over-all output was reduced but the high frequencies were attenuated to a greater degree, making the surface noise less audible. Steel needles were used most commonly during this period, although "low-noise" fibre or thorn needles, more compliant than steel, also were used.

Steel needles had to be changed after every play with abrasive-filled records. In the 1930s chrome-plated needles, which could be used somewhat longer, were introduced, and needles with hard metal tips such as osmium were also available. With the advent of light-weight pickups, jeweled styli (sapphire and diamond) became predominant.

Record styli are made to precise specifications. The point should be spherical, tapering off to a 50° cone. For the 78-r.p.m. record a 0.003-in. point radius is desirable, and for the fine-groove records a 0.001-in. radius. Specifications for the stereophonic records call for a stylus point with a maximum radius of 0.0008 in.

There is no permanent stylus. Even a diamond point will wear with time. With light pickups a diamond stylus should perform satisfactorily for 100–500 hours of playing time, a sapphire stylus about one-fifth of that time.

The needle should make contact on the sides of the groove for best reproduction. As the stylus wears, its sides become flat and the stylus rides more closely to the bottom of the groove. A stylus

riding on the bottom of a record groove results in noisy and distorted reproduction. (A. M. MA.)

2. Reproducer or Pickup.—A phonograph pickup is a device which, when actuated by the record groove, will produce a usable signal proportional to the signal (music) recorded in the groove. Common forms of phonograph pickups produce an electric signal proportional to the amplitude or velocity of the signal in the record groove.

Phonograph pickup designers have explored nearly all of the known principles of electric generation, including the piezoelectric effect from certain crystals, variable resistance, variable capacity, variable magnetic flux cutting, variable magnetic reluctance and variable light-beam photoelectric effects. In general, it is possible to design a pickup using any principle that will produce an electrical signal from a mechanical signal. The selection of the principle and the design of the pickup is usually determined by cost, environmental conditions, etc.

Because of relatively high electric output, crystals of Rochelle salts, properly cut and designed into a pickup, have been extensively used in low- to medium-priced phonographs. Barium titanate and lead titanate zirconate also have been used, as these materials are less affected by moisture and temperature variations than Rochelle salts (*see* PIEZOELECTRICITY). Mechano-electromagnetic principles have found considerable use, moving-iron and moving-coil devices being commonest. Mechano-electro-capacity principles also have been employed.

Pickup designers, for the most part, have directed their efforts toward designs of low cost, low mechanical impedance, low distortion and high reliability. Low mechanical impedance has received considerable attention because its attainment permits a low value of stylus force. The less the stylus force, the less will be the wear of the stylus and the record groove. Concentrated effort on the part of pickup designers reduced the mechanical impedance to the point where only a fraction of an ounce of stylus force was necessary to hold the stylus in contact with the walls of the groove. It was this development which permitted the use of clear vinylite record materials and a stylus radius of 0.001 in. or less. To appreciate the magnitude of this accomplishment, it is only necessary to consider that many mechano-acoustic pickups required a stylus force of over six ounces with a stylus radius of 0.003 in.

Stereophonic pickup design followed the same basic principles used for monophonic pickups. The so-called universal pickups used for hill-and-dale and lateral transcription equipment were the forerunners of the 45°–45° stereophonic pickups. In the stereophonic pickup, it was the design objective to produce two independent signals using a single stylus actuated by two independent signals recorded in a single record groove. Thus the pickup has two independent electric generating units connected to and actuated by a common stylus.

3. Record Changers.—A record changer is a mechanism designed to permit a stack of selected records to be played without further attention.

While a number of early patents were granted on automatic record-changing devices, very few machines reached the hands of the public until after the mid-1930s. The low-cost, single-play phonograph attachment, for use with a radio, stimulated interest in the playing of records. As record collections grew, the need for record changers became apparent. By 1940 many manufacturers were equipping their phonographs with record changers.

The record-changing mechanisms were of varied designs. Commonest in the early period was the edge-selector type in which the records were placed over the centre spindle and supported at their circumference on two or more shelves. Blades or knives, above the shelves, sliced in between the bottom record and the next above to drop the bottom record onto the turntable. In another design the record stack was supported at the centre on an offset portion of the spindle and at the circumference by a shelf. The top portion of the spindle was tilted slightly to provide stability to the stack. The shelf support included a mechanism designed to push the bottom record from the off-set portion of the spindle. Edges and centre holes of shellac records were damaged by these types of mechanisms.

After World War II, many improvements were made in record-changer mechanisms. The use of vinylite record material practically eliminated damage to the record by the selector mechanism. In addition, improvements were made in the turntable drive system, tone arm, tone arm landing and tripping mechanisms, etc. (A. D. B.)

4. Phonograph Motors and Drive Systems.—The first experimental machines were hand cranked, usually with some steadying effect by flywheels, but in one of his early patents Edison stressed the importance of correct and uniform speed. Battery-operated electric motors were soon used, but these were sensitive to changes in load and voltage; flyball governors were used to reduce speed variations. The most satisfactory of these governors were those with a friction disk, the friction of which increased rapidly if the speed exceeded the desired value. While Edison was reluctant to give up the electric motor, a spring-driven, governed motor developed by Frank Capp, a pioneer in many phonograph improvements, was demonstrated to Edison and adopted, and spring motors also were developed by the Columbia company and by Berliner. At the end of 1896 all three companies were using governed spring motors.

For recording, weight-driven machines with friction governors were used for many years. The weight supplied a constant torque, and the governor was connected to the turntable spindle through a worm gear. These were precision-built machines.

Electric motors did not come into very extensive use until radio-phonograph combinations were introduced, and then for many years the motor served only to provide a reasonably uniform driving torque, and friction governors, geared to the turntable, regulated the speed. The induction disk motor (like those used in watt-hour meters) was widely used in this manner. Small, high-speed, split-phase or shaded-pole induction motors with governors were among the many forms used during the 1930s, and a true synchronous motor, resembling a clock motor, was used in some machines. The latter had a multitoothed steel disk which, once started, was kept rotating by the intermittent pull of its toothed pole pieces.

"Rumble" due to vibration of the turntable or pickup pivot presents a problem. The vibration is primarily caused by the high-speed motor and transmitted through the motor supports or the speed-reduction system. Cushion mounting of the motor is therefore necessary. Problems arise because the ear is especially sensitive to slow pitch fluctuations. Successful filtering is increasingly difficult as the frequency of the disturbance is lowered. Belting between motor and turntable can give excellent results in reducing rumble. Transmission of rumble by the belts can be almost completely avoided. Very light, thin, flexible belts of exceptional uniformity are required, especially if one of the pulleys is small; usually, two stages of reduction are used. Friction drives with rubber tires also are widely used because the rubber tires can be ground to a high degree of concentricity. By grinding the end of the motor shaft in its own bearings (after balancing the motor), the shaft end can serve very satisfactorily for the first unit of the drive train, even though it is as small as $\frac{3}{16}$ in. in diameter. The inside of the flanged turntable, machined to concentricity, can be the final friction drive surface. The rubber tires can then be on the intermediate wheels. Since the load is light, the slip or "creep" is negligible. (E. W. KE.)

V. MAGNETIC RECORDING

The advantages of magnetic recording were quickly appreciated by the phonograph industry, once its excellent low-noise and audio-quality characteristics had been demonstrated. Greater recording time, immediate playback, the possibility of erasing and reusing the medium and the feasibility of editing, a feature never possible in disc recording, soon made magnetic tape a popular medium for phonograph recordings and broadcasting. In a very short time all original recordings were being made on magnetic tape; these were transferred, after editing, to discs.

Magnetic tape also offered another means of bringing recorded music into the home, with the advantage that more than one track

GLASS WINDOWS AT LEFT SHOW ROOM TO ISOLATE VOCALIST AND AT RIGHT CONTROL ROOM WHERE SOUND FROM EIGHT SEPARATE AUDIO CHANNELS (FOUR WITH ECHO AND FOUR WITHOUT) IS MIXED AND FED TO A FOUR-TRACK MAGNETIC TAPE RECORDING MACHINE

could be recorded simultaneously, thus permitting stereophonic recording. Prerecorded tapes soon became available for home use for both monophonic and stereophonic reproduction. These appeared as two-track recordings on tape ¼ in. wide, on spools either seven or five inches in diameter, depending upon the playing time. The operating speed was 7½ in. per second. For monophonic recordings each track was used separately and a total playing time of approximately one hour was possible. For stereophonic recordings where both tracks were used simultaneously the total playing time was about 30 minutes. After tape having a thinner base became available, the playing time was increased by about 50%, thus permitting a playing time of about 45 min. for a stereophonic recording. *See* TAPE RECORDING, MAGNETIC.

(H. E. R.)

VI. PHONOGRAPH MUSIC

The day in 1877 when Thomas Edison reproduced his own voice on a tin-foil cylinder, reciting "Mary Had a Little Lamb," marked the beginning of an activity with potentialities unforeseeable even in the most extravagant dreams. Edison's "talking machine," generally regarded as an elaborate toy but offering the novelty of hearing one's voice reproduced, preserved the voices of many prominent people of the time, such as those of William Gladstone, P. T. Barnum and Robert Browning. An early musical recording was that of Brahms playing one of his own works.

Commercial recording was established in the 1890s and in spite of quantity production problems had an amazing growth. Many early records were of vaudeville skits, monologues and descriptive accounts, with some musical selections by bands, whistlers and singers. By the early 1900s many first-rank artists were to be heard on both discs and cylinders. The fact that the voice reproduced better than instruments made singers much in demand. Among the earliest artists to record were Medea Figner, Nikolay Figner and Enrico Caruso, whose great success undoubtedly influenced other artists favourably. In the United States, "Celebrity Disks" were issued by the Columbia company, followed by the Red Seal list of Victor. By 1910 nearly every first-ranking singer was represented on records. Orchestral accompaniment to vocal records began in 1906 after an unsuccessful start in 1900. Many instruments did not reproduce well; since brass instruments recorded better than others, there was a tendency toward their overemphasis, the musical result often being far removed from the composer's intention. Orchestras had to be small because of the necessity for grouping the musicians close around the recording horn. Among the first instrumental soloists to record were Sarasate (Pablo de Sarasate y Navascues), Joseph Joachim, Raoul Pugno, Fritz Kreisler, Jan Kubelik, Ignace Paderewski, Eugène Ysaÿe, Vladimir von Pachmann and Efrem Zimbalist.

Recording of orchestral repertory began in London in 1909 when the Odeon company issued the Tchaikovsky *Nutcracker Suite,* played by the London Palace orchestra under Herman Finck. The increased interest in instrumental recording brought forth a variety of works, played by various orchestras, often in condensed versions. In the United States in 1912, the Columbia company engaged Felix von Weingartner to conduct an enlarged staff orchestra for several discs. In 1917 Columbia engaged the Chicago symphony under Frederick Stock, the Cincinnati symphony under Ernst Kunwald and the New York Philharmonic under Josef Stransky; and in 1918 Victor began a series by the Boston symphony under Karl Muck and by the Philadelphia orchestra under Leopold Stokowski. Chamber music made its appearance in 1916 in Europe with recordings by the London string quartet. An occasional full-length large work was recorded, one of the earliest being a La Scala performance of Leoncavallo's opera *I Pagliacci* under the composer's direction. The main interest, however, seemed to centre on the artist rather than the music.

The introduction of electrical recording in the 1920s marked the beginning of the second period of phonograph development, during which the emphasis shifted to production of complete works. The use of microphones eliminated crowding around a recording horn; this, along with improved quality of sound and increased tonal range, opened up new fields of instrumental literature. Record catalogues listed complete symphonies, operas and chamber works by nearly all the well-known composers of the past as well as works by many contemporaries. The composer and the composition, rather than the artist, became the chief points of interest. Ironically, progress in electronics, which made such technical advances possible in the recording field, served to work against increased use of the phonograph because of the rapid growth of radio broadcasting. World War II was another restraining influence, though the end of the war brought an increased activity in recording and several improvements in reproduction techniques, such as full-frequency-range recording introduced in England by the Decca company. The real revolution, which marked the beginning of the third great period of phonograph history, was the introduction of fine-groove records in 1948. Their almost total lack of surface noise, improved faithfulness of reproduction, and the fact that they allowed recording of complete works on one or two sides of a single record meant that the fine-groove records almost immediately supplanted older types.

A development of equal importance was the introduction of magnetic tape for making original recordings. In a time of rising production costs, the advantages of tape were obvious: no longer did soloists and orchestras have to repeat compositions many times to achieve a performance satisfactory for public sale on records; instead, sections containing flaws could be rerecorded and these sections could then be patched into the tape to make a final master tape from which the master disc was transcribed. Some critics maintained that the too-perfect results thus obtained lacked the realism of actual performance, but the reaction of musicians and record purchasers was in general enthusiastic. In addition, the mobility of tape-recording equipment made it much easier to record actual performances in concert halls and theatres, thus putting on discs many performances otherwise unattainable.

Tape-recording and playback equipment was available for home use, in both monophonic and stereophonic types, and recording companies offered extensive lists of prerecorded tapes; in general, when reproduced on good equipment, the quality of these tapes exceeded that of the best disc recordings.

The educational possibilities of the phonograph were realized early in such collections as the *History of Music by Eye and Ear,* edited by Percy Scholes, *Two Thousand Years of Music,* edited by Curt Sachs, and numerous other sets of similar nature. Other special issues were tests for measuring musical talent or accomplishment, discs for technical instruction of various kinds, missing-part records for learning chamber music and numerous others. A remarkable result of the new recording techniques was the issuing of many of what might be termed rerecorded old acoustical records, making it possible to hear artists of earlier days under more favourable conditions of reproduction. Popular music, of course, was one of the mainstays of the industry, the material made available in this field being even more complete than the extensive

listing of the classical field. The popularity of dance bands on records began in 1913, gaining increasing interest each year. Folk songs from nearly every area of the world appeared both as special studies and as regular releases. Nonmusical lists, in addition to the usual numerous sketches, monologues and similar short offerings, showed an increasing number of complete plays and musical shows, as well as recordings of noted poets and authors reading from their own works. Of documentary importance as well as general interest were the collections of statements by prominent people and comments on newsworthy current events. Foreign language and other instruction, children's stories and Bible stories were among the many choices of instruction and entertainment made available. An important development for scholars was the establishment of archives by museums and libraries for preserving old and new records for their historical value.

Information regarding available records was to be found in magazines such as the *American Record Guide*, the *Gramophone* and *Disques*, devoted solely to dispensing record information, as well as in others having record sections. Numerous books on the subject were also published, some surveying the entire field and others dealing with only limited portions. (AY. D.)

PHONOLITE, a group of alkaline lavas rich in nephelite (*q.v.*) and sanidine, an alkali (potash) feldspar (*q.v.*). The name is a Greek rendition of the German *Klingstein* (*phone*, "sound," and *lithos*, "stone"), referring to fine-grained compact lavas which split into thin, tough plates and give out a ringing sound when struck with a hammer. The presence of a feldspathoid mineral was suspected from gelatinization tests (decomposition by hydrochloric acid, with separation of gelatinous silica) as early as 1828, but it was not until 1867 that nephelite was shown to be a major constituent of the matrix.

The most important constituent of phonolite is alkali-feldspar, either sanidine or anorthoclase, which forms not only the bulk of the ground mass, but most of the large crystals in porphyritic varieties.

Nephelite rarely appears in large crystals but may occur either interstitially or in well-formed microphenocrysts. The principal ferromagnesian mineral is a pyroxene, titanaugite, aegirine or cores of the former mantled by the latter. Pyroxene in phenocrysts is sharply euhedral; in the matrix it occurs characteristically in slender unterminated needles, often so abundant as to impart a green colour to the rock.

Amphibole (*q.v.*) is practically confined to phenocrysts and is usually an alkaline variety, barkevikite, riebeckite or arfvedsonite. Feldspathoids other than nephelite may be present in accessory amount, the commonest being noselite, sodalite (*q.v.*) and leucite (*q.v.*). Glass has been reported occasionally but only in small amount.

Occurrences.—Most phonolites are of Tertiary or Recent age, but excellent examples are found at several localities in the Carboniferous strata of Scotland and also of Brazil. In terms of the numbers of recorded occurrences, though not perhaps in total volume, Tertiary or Recent phonolites are common in Europe, in the Auvergne (Mont Dore), the Eifel, the Laacher See and Bohemia. They have been described from a number of sites in the Mediterranean area, chiefly in Italy, as well as from Cripple Creek in Colorado, and the Black Hills, South Dakota. The famous Devils Tower, Wyoming, is variously described as tinguaite or phonolite, depending on whether it is considered a plug or a flow.

Leucite phonolites are perhaps best known from the vicinity of Naples. Apachite, from the Apache Mountains, west Texas, is an amphibole phonolite. Kenyite, from Mt. Kenya, east Africa, is rich in cossyrite and olivine. The phonolite of Ölbruck, Ger., a rather popular local building stone, is said to contain about 15% of noselite and 8% of leucite.

Phonolitic trachytes are found on St. Helena and a number of other oceanic islands. (F. Cs.)

PHORMION (probably died 428 B.C.), Athenian admiral, son of Asopius. He first appears in 440 B.C. among the generals bringing reinforcements to the Athenian troops before Samos. Later he was sent to help the Acarnanians and Amphilochians against Ambracia; this was the origin of Athens' useful alliance with Acarnania. In 432, after Callias' death before Potidaea, Phormion went out with fresh forces and completed the circumvallation of the city. He was still there in 431, but at the end of 430 he was sent with 20 ships to Naupactus to block the entrance to the Gulf of Corinth. There in summer 429 he won two brilliant victories. In the first he defeated 47 Peloponnesian ships on their way to support the Spartan Cnemus' campaign in Acarnania; in the second, Cnemus' fleet of 77 attacked him in the narrows, but he turned and routed them. The next spring he returned to Athens. In summer 428 his son Asopius was sent out, the Acarnanians having asked for a general from Phormion's family, which suggests that he himself had died. *See* PELOPONNESIAN WAR. (A. As.)

PHORMIUM (NEW ZEALAND FLAX; also termed NEW ZEALAND HEMP). The plant (*Phormium tenax*) is a perennial of the Liliaceae family and is propagated either by rhizomes or by seed. While termed "New Zealand flax" and also "New Zealand hemp," the plant has no relationship to either flax (*Linum usitatissimum*) or hemp (*Cannabis sativa*). Phormium is a native of New Zealand and, while known to be adapted in many other countries, is not commonly grown for commercial fibre production in any country other than New Zealand.

The thick sword-shaped leaves grow in tufts from the tips of the rhizomes and reach a length of four to six feet. The flowering stem, which also starts from the tip of the rhizome, grows out through the centre of the tuft of leaves and reaches a height of 5 to 15 ft. The flowers are usually cross-pollinated though some self-pollination occurs. The parts above ground die soon after the flowering stage, but the plant continues to live from year to year by new growth from short, thick underground stems (rhizomes).

Much of the phormium fibre of commerce has come from harvesting the volunteer growth, but considerable quantities have been obtained from cultivated fields. The crop is adapted to a wide range of New Zealand soils, but the greatest yields have been obtained from well-drained swamp lands.

The plant is grown principally for the fibre which develops in the leaves, and which is separated from the nonfibrous tissues by a process of scraping and washing. This processing is done in fibre mills by means of special machines designed for the purpose.

The cleaned, dried fibre is arranged in hands ("heads") and then packed in bales, in which form it is exported. The fibre is similar in appearance to such other leaf fibres as abaca (Manila hemp), henequen (Yucatan sisal) and "true" sisal. Its principal use has been for twines and ropes.

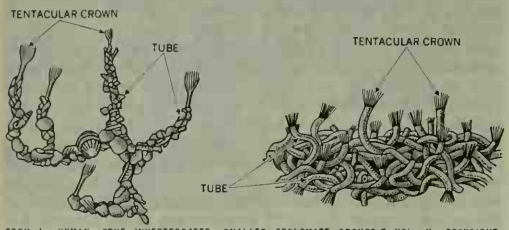
See H. J. Critchfield, "Phormium Tenax—New Zealand's Native Hard Fiber," *Econ. Bot.*, vol. 5 (1951). (A. H. WT.)

PHORONEUS, in Greek legend a very early king of Argos (*q.v.*), the son of Inachus. Inachus was, in one tradition, the earliest of all Hellenic rulers, but he was sometimes admitted to be simply a river-god, so Phoroneus was the first mortal king. The only legend extant about Phoroneus is that he and two river-gods had to decide between Poseidon and Hera as the deity of the land. They chose Hera, and Poseidon took his vengeance by depriving the Argolid of water. (Traditionally from Homer onward Argos was "the very thirsty" land.) (H. W. PA.)

PHORONIDA is a phylum of small, marine, wormlike animals which live in self-secreted tubes embedded in the sea bottom or attached to solid surfaces. They are found in shallow tropical and temperate waters of many parts of the world—Europe, North and South America, Australia, South Africa and Asia. Phoronids, constituting a small and relatively homogeneous group, are considered to be a separate phylum because they are structurally unique; they cannot clearly be related to any other group of ani-

mals. In the past, however, attempts were made to relate them to the Annelida, Mollusca and Chordata among other phyla. Two genera, *Phoronis* and *Phoronopsis*, and about 16 species are recognized.

Many phoronids occur in vertical tubes placed just below the



FROM L. HYMAN, "THE INVERTEBRATES: SMALLER COELOMATE GROUPS," VOL. V; COPYRIGHT, 1959, MCGRAW-HILL BOOK CO. USED BY PERMISSION

FIG. 1.—(LEFT) PHORONIS PSAMMOPHILA, WITH TUBES COATED WITH ROCK GRAINS AND SHELLS; (RIGHT) AGGREGATION OF P. HIPPOCREPIA

surface in intertidal or subtidal mud or sand flats. Other species form dense feltlike masses of intertwined tubes attached to rocks, pilings or logs in shallow water. In both these cases the tubes are encrusted with small particles of sand or shell. A third living habit concerns those phoronids which are found living inside closely fitting channels in limestone rock or in the discarded shells of bivalve mollusks. Phoronids appear to be widely distributed in temperate and tropical seas, but there are no records from polar regions.

Structure and Function.—In all phoronids the body is more or less elongate—most species ranging in length from less than a centimetre to 20 cm.—and bears a crown of tentacles at one end. The tentacles are arranged in a double row surrounding the usually crescent-shaped mouth. The mouth is partly covered by a flap of tissue known as the epistome. The anus occurs at the same end of the body as the mouth and is borne on a small papilla located immediately outside the double row of tentacles. The digestive tract is therefore U shaped. The tentacles may form a slightly indented circle or a complex double spiral. Situated near the bases of the tentacles is a supporting structure made of connective tissue and known as the lophophore. Depending on the species, there may be from about 50 to over 300 tentacles, each one bearing fine hairs or cilia. The movements of the cilia create currents which carry food particles from the surrounding water into the mouth and waft waste particles away from the anus. Feeding and excretory currents have not been studied in great detail.

The digestive tract consists of esophagus, stomach, intestine and rectum. These various regions differ from one another in size and in the nature of the cells forming the internal lining. In some species there is a distinct muscular valve between the esophagus and the stomach. The junction of the stomach and intestine occurs at the proximal end of the body, that is, the end which does not bear tentacles, mouth and anus. The tentacular end of the body is known as the distal end. The food seems to consist chiefly of microscopic phytoplankton. Diatom shells may frequently be found in the digestive tract and in the fecal pellets.

There is a system of blood vessels in which circulate elliptical, nucleated corpuscles containing the red pigment hemoglobin, similar to the hemoglobin found in human blood. Two longitudinal vessels, known as the afferent and efferent vessels, are continuous with one another at the proximal end of the body. At the distal end both vessels connect with a pair of semicircular vessels located at the level of the lophophore, immediately below the tentacles. Within each tentacle is a single, blind vessel which branches into two at its base and so connects with both semicircular vessels. In the living animal the red blood corpuscles can easily be seen pulsating up and down in the transparent tentacular vessels. Associated with the longitudinal vessels are a blood sinus surrounding the digestive tract and a large number of short, blind vessels which are particularly numerous in, or may be restricted to, the proximal end of the body. Associated with these blood vessels is a jellylike tissue known as the fat body or the vasoperitoneal tissue. Among the large, semifluid cells of this tissue are a number of granules of varying size and shape. Some of them probably consist of guanine and may be considered to be deposits of waste material. Others may represent the products of hemoglobin breakdown.

The body cavity is subdivided by a series of long, thin membranes known as mesenteries, which extend from the digestive tract to the body wall. In most phoronids there are four such mesenteries dividing the body cavity into four longitudinal chambers. There is also a horizontal mesentery near the tentacular end of the body separating a lophophoral cavity from the four larger cavities occupying the rest of the body. In the living phoronid the body cavity is filled with a fluid which is responsible for the turgor or relative firmness of the otherwise soft body.

On either side of the papilla which bears the anus is a small pore connecting with an organ of excretion known as a nephridium. Each nephridium consists of a duct, coiled once on itself and continuous with a pair of funnels opening into two of the four larger body cavities. The walls of the funnels tend to be much folded and are heavily ciliated. The activity of the cilia probably creates a current in the body cavities which carries fluid waste into the funnels and eventually to the outside via the nephridial pores.

The body wall consists of an outer layer of epithelial cells and two layers of muscle fibres: the outer circular and the inner longitudinal. Many of the epithelial cells secrete a fluid which is used by the animal to build the tightly fitting chitinous tube in which it lives. The freshly secreted fluid is transparent and sticky, but on contact with water it gradually hardens. In some species the secreted tube becomes encrusted with tiny grains of sand, mud or shell which adhere to the surface. In many such cases the cemented particles are arranged to form a very even and beautiful mosaic. The tube is in most cases closed at the proximal end; from the distal open end the body may be extended a rather long distance. Most phoronids can shorten or lengthen the body considerably; this is accomplished by the muscles in the body wall contracting against the fluid in the body cavity.

The nervous system is also located in the body wall and consists chiefly of a nerve net lying immediately beneath the epithelial cells. This nerve net is continuous with a more dense concentra-

FIG. 2.—PHORONIS ARCHITECTA (LEFT) LOOKING INTO THE TENTACULAR CROWN OF MATURE ADULT WITH FULLY DEVELOPED LOPHOPHORE. ONLY THE BASES OF THE OUTER TENTACLES ARE SHOWN. (RIGHT) YOUNG ADULT

tion of nervous tissue in the horizontal mesentery. Extending from this region and running along, in or beneath the epidermis are one or two giant nerve fibres which taper and end near the proximal end of the body. The giant nerve fibres are known in all but one species and are probably related to the animal's ability to withdraw the body into the tube with great rapidity.

Reproduction and Natural History.—Reproductive tissue is formed from cells located on the thin walls of the short, blind blood vessels in the proximal part of the body. The phylum includes species in which individual animals are either male or female and other species in which each animal is a hermaphrodite and carries both male and female organs. As the reproductive tissue grows along the walls of the blood vessels it displaces the surrounding vasoperitoneal tissue which shrinks proportionately. When the ova and spermatozoa are ripe, they are shed into the body cavity, find their way to the nephridial funnels and pass through these organs to the outside. In some species the sex cells simply pass out into the surrounding water where early development takes place. In others the ova are retained in the tentacular crown of the adult until each has developed into a tiny, transparent, free-swimming larva. The type of larva characteristic of the phylum Phoronida, an actinotroch larva, is distinguished chiefly by a ring of ciliated tentacles and a flap of tissue over the mouth.

The actinotroch larva may spend over a month swimming freely, feeding on plankton and increasing considerably in size. Eventually, it settles on the bottom and undergoes a metamorphosis whereby it is rapidly and drastically changed into a tiny adult phoronid. All phoronids can reproduce sexually, and in most cases the life history includes an actinotroch larva. Some species are known to reproduce asexually as well, by the apparently simple process of dividing the body into a number of segments, each of which then breaks off and develops into a new adult.

See L. H. Hyman, *The Invertebrates*, vol. 5 (1959). (J. R. Ma.)

PHORORHACOS, a genus of extinct flightless birds of large size, known from Tertiary formations in southern South America. They appear to have been remotely related to the living seriema (*q.v.; Cariama cristata*) of that region. *Phororhacos* (family Phororhacidae) is included in the order Gruiformes, to which the living cranes (Gruidae) and rails (Rallidae) belong. Numerous parts of specimens have been found, and the most complete fossil specimen is *P. inflatus*, of which head, pelvis, limb bones and some of the vertebrae are recorded.

BY COURTESY OF BRITISH MUSEUM (NATURAL HISTORY)

RESTORATION DRAWING OF PHORORHACOS, AN EXTINCT BIRD

The skull in this bird is about 13 in. long, with the maxilla high in profile, much compressed laterally and terminating in a strong hook; the heavy mandible is curved upward at the tip. The long legs are strong though slender, the tibia being 15–16 in. long. The small size of the wing elements, the form of the shoulder girdle and the skeleton as a whole indicate a cursorial species unable to fly. From the form of the bill, the bird was apparently a formidable predator. It is estimated to have stood about three feet high at the shoulder.

The skull of another species, *P. longissimus*, is about 24 in. long with the beak 10 in. high, indicating a bird of gigantic size. An allied genus, *Andrewsornis*, described by B. Patterson from an incomplete skull and other fragments, had a slender 15-in.-long mandible and indications of a stronger wing. Another genus, *Mesembriornis*, has been recognized from Pliocene deposits (about 10,000,000 years ago). Several workers have described a dozen or more species from fragmentary bones in addition to those mentioned, but the relationships of several of these are doubtful. The family, the earliest known representative of which appeared in the latter part of the Oligocene epoch (more than 30,000,000 years ago), continued into the early Pliocene.

See Karman Lambrecht, *Handbuch der Palaeornithologie*, pp. 494–516, fig. 147–154 (1933); Bryan Patterson, "A New Phororhacoid Bird From the Deseado Formation of Patagonia," *Field Museum of Natural History Geological Series*, vol. 8, no. 8, pp. 49–54 (1941). (A. Wt.)

PHOSGENE (Carbonyl Chloride) is a colourless, extremely poisonous gas, about three and one-half times heavier than air, having a stifling, nauseating odour resembling sour green corn or musty hay. It is a lung injurant and even in small amounts may prove to be very harmful. It may act slowly, its full effects sometimes developing several hours after inhalation. It first came into prominence in World War I, being used as an offensive poison gas either alone or mixed with chlorine.

Phosgene was first synthesized in 1812 by John Davy, the British chemist, by the reaction of carbon monoxide and chlorine in the presence of sunlight; hence the derivation of its name from the Greek *Phos* (light) and *genes* (born). It is manufactured by passing the two gases over a specially prepared charcoal catalyst. The reaction is expressed chemically by the equation $CO + Cl_2 \rightarrow COCl_2$. It has also been manufactured by the reaction of fuming sulfuric acid on carbon tetrachloride. The preparation of a number of pharmaceuticals, industrial chemicals, and dyestuffs involves its use.

Phosgene is active chemically; it fumes in moist air and reacts with water to form hydrogen chloride (hydrochloric, or muriatic, acid) and carbon dioxide: $COCl_2 + H_2O \rightarrow 2HCl + CO_2$. It is sometimes formed when chlorinated hydrocarbons are heated; *e.g.*, when carbon tetrachloride is used as a fire extinguisher. Phosgene gas can be readily condensed to a liquid, which boils at 8.2° C (46.8° F) at atmospheric pressure. It is ordinarily stored and transported under slight pressure in steel cylinders, although under certain circumstances it is stored and transported as a solution in toluene. (A. V. C.)

PHOSPHATE ROCK, a sedimentary formation of marine phosphorite usually interbedded with shales or limestones. It occurs in many parts of the world and is mined in North Africa, Germany, the U.S.S.R., the United States and several other countries. The name collophane is sometimes given to the massive, seemingly noncrystalline apatite (*q.v.*) that is the essential constituent of phosphate rock. It is composed largely of calcium phosphate, an important ingredient of bones, teeth and many shells. Other components include lime, silica, fluorine and carbonaceous (carbonate) matter. Phosphate rock is used in the preparation of fertilizers and as a source of phosphorus for matches and of phosphoric acids used in the chemical industries. It originated on the sea floor during several geologic periods at times and under conditions that favoured precipitation of the apatite from solution but retarded the addition of much land waste. For uses, occurrences, production, etc. *see* Fertilizers and Manures. *See* also Mineral Phosphates; Phosphorus. (J. T. P.; X.)

PHOSPHATES: *see* Phosphoric Acids and Phosphates.

PHOSPHORESCENCE: *see* Bioluminescence; Luminescence.

PHOSPHORIC ACIDS AND PHOSPHATES. Phosphates are salts of phosphoric acid. Phosphoric oxide, P_2O_5 or P_4O_{10}, combines with water in three proportions to form $H_2O{\cdot}P_2O_5$ or HPO_3, metaphosphoric acid; $2H_2O{\cdot}P_2O_5$ or $H_4P_2O_7$, pyrophosphoric acid; and $3H_2O{\cdot}P_2O_5$ or H_3PO_4, orthophosphoric or ordinary phosphoric acid. These acids each give origin to several series of salts, those of ordinary phosphoric acid being the most important, especially as fertilizers. *See* also Phosphorus: *The Oxyacids of Phosphorus;* Fertilizers and Manures: *Phosphorus-Supplying Fertilizers.*

Orthophosphoric acid, H_3PO_4, a tribasic acid, is obtained by boiling a solution of the pentoxide in water; by oxidizing red phosphorus with nitric acid, or white phosphorus under the surface of water by bromine or iodine; and also by decomposing a mineral phosphate with sulfuric acid. It usually forms a thin syrup which on concentration in a vacuum over sulfuric acid deposits hard, transparent, rhombic prisms which melt at 41.7° C. After long heating the syrup is partially converted into pyrophosphoric and metaphosphoric acids, but on addition of water and

boiling the ortho acid is reformed. It gives origin to three classes of salts: $M'H_2PO_4$ or $M''(H_2PO_4)_2$; M'_2HPO_4 or $M''HPO_4$; and M'_3PO_4, $M''_3(PO_3)_2$ or $M'''PO_4$, wherein M′, M″, M‴ denote a univalent, bivalent and trivalent metal. These correspond to H_3PO_4 in which one, two or three atoms of hydrogen, respectively, have been replaced by a metal. The three principal groups differ remarkably in their behaviour toward indicators. Those of the first type are strongly acid, the second are neutral or faintly alkaline, while the third are strongly alkaline and are decomposed by carbon dioxide: $Na_3PO_4 + CO_2 + H_2O \rightarrow NaHCO_3 + Na_2HPO_4$. The salts of the types NaH_2PO_4 and $CaH_4P_2O_8$ may be obtained in crystal form, but those of the heavy metals are stable only when in solution. All soluble orthophosphates give with silver nitrate a characteristic yellow precipitate of silver phosphate, Ag_3PO_4, soluble in ammonia and in nitric acid. Since the reaction with the acid salts is attended by liberation of nitric acid: $NaH_2PO_4 + 3AgNO_3 \rightarrow Ag_3PO_4 + NaNO_3 + 2HNO_3$, $Na_2HPO_4 + 3AgNO_3 \rightarrow Ag_3PO_4 + 2NaNO_3 + HNO_3$, it is necessary to neutralize the nitric acid if the complete precipitation of the phosphoric acid is desired.

The three series also differ when heated: the trimetallic salts containing fixed bases are unaltered, while the monometallic and dimetallic salts yield metaphosphates and pyrophosphates, respectively. Other common precipitants of phosphoric acid or its salts in solution are: ammonium molybdate in nitric acid, which on heating gives a canary-yellow precipitate of ammonium phosphomolybdate, $(NH_4)_3PO_4 \cdot 12MoO_3$, insoluble in acids but readily soluble in ammonia; magnesium chloride, ammonium chloride and ammonia, which on standing in a warm place give a white crystalline precipitate of magnesium ammonium phosphate, $Mg(NH_4)PO_4 \cdot 6H_2O$, which is soluble in acids but highly insoluble in ammonia solutions, and on heating to redness gives magnesium pyrophosphate, $Mg_2P_2O_7$.

Of the organic phosphates, triphenyl phosphate, $(C_6H_5)_3PO_4$, is important, acting as a filler or "dope," and as a plasticizer. It is a colourless solid of m.p. 53° C and b.p. 245° C.

Pyrophosphoric acid, $H_4P_2O_7$, is a tetrabasic acid which may be regarded as derived by eliminating a molecule of water between two molecules of ordinary phosphoric acid; its constitution may therefore be written $(HO)_2OP{\cdot}O{\cdot}PO(OH)_2$. It may be obtained as a glassy mass, indistinguishable from metaphosphoric acid, by heating phosphoric acid to 215° C. When boiled with water it forms the ortho acid, and when heated to redness, the meta acid. After neutralization, it gives a white precipitate with silver nitrate. Being a tetrabasic acid it can form four classes of salts; for example, the four sodium salts $Na_4P_2O_7$, $Na_3HP_2O_7$, $Na_2H_2P_2O_7$ and $NaH_3P_2O_7$ are known. The most important is the normal salt, $Na_4P_2O_7$, which is readily obtained by heating disodium orthophosphate, Na_2HPO_4. It forms monoclinic prisms (with $10H_2O$) which are permanent in air.

All soluble pyrophosphates when boiled with water are converted into orthophosphates.

Metaphosphoric acid, HPO_3, or more correctly $H_2P_2O_6$ as determined by vapour density, is a monobasic acid which may be regarded as derived from orthophosphoric acid by the abstraction of one molecule of water, thus $H_3PO_4 - H_2O \rightarrow HPO_3$; its constitution is therefore $(HO)PO_2$. The acid is formed by dissolving phosphorus pentoxide in cold water, or by strongly heating orthophosphoric acid. It forms a colourless vitreous mass, hence its name "glacial phosphoric acid." It is readily soluble in water, the solution being gradually transformed into the ortho acid, a reaction which proceeds much more rapidly on boiling. Although the acid is monobasic, salts of polymeric forms exist of the types $(MPO_3)_n$, where n may be 1, 2, 3, 4 or 6. They may be obtained by heating a monometallic orthophosphate of a fixed base, or a dimetallic orthophosphate of one fixed and one volatile base; *e.g.*, microcosmic salt: $MH_2PO_4 \rightarrow MPO_3 + H_2O$; $(NH_4)NaHPO_4 \rightarrow NaPO_3 + NH_3 + H_2O$. The salts are usually noncrystalline and fusible. Their solutions on boiling yield orthophosphates, while those of heavy metals give a trimetallic orthophosphate and orthophosphoric acid: $3AgPO_3 + 3H_2O \rightarrow Ag_3PO_4 + 2H_3PO_4$. Metaphosphoric acid can be distinguished from the other two acids by its power of coagulating albumen, and by not being precipitated by magnesium and ammonium chlorides in the presence of ammonia.

For perphosphoric acids, *see* PHOSPHORUS.

PHOSPHORITE, impure massive carbonate- and phosphate-bearing apatite (*q.v.*), or phosphate rock (*q.v.*). *See* also FERTILIZERS AND MANURES; MINERAL PHOSPHATES.

PHOSPHORUS. Phosphorus was first prepared in elemental form in 1669 by the alchemist Hennig Brand of Hamburg, who used the residue from evaporated urine as the source of the element. News of the discovery soon spread over Germany. Brand did not disclose to the public his method of producing phosphorus but he sold the secret to Johann Krafft of Dresden. The chemist Johann Kunckel sought to learn from Brand the method used, but found only that urine had been used as the source of the phosphorus. With this information Kunckel was able, after many trials, to duplicate Brand's accomplishment. Kunckel likewise attempted to keep the process a secret and, like Brand and Krafft, tried at various times to sell it.

Krafft exhibited samples of phosphorus in many countries; in 1677 he performed experiments with it before members of the Royal society in England. A few years later the British chemist Robert Boyle devised a method of preparing the element, and deposited with the secretary of the Royal society a description of his method which, however, was not published at the time. Boyle had little or no interest in alchemy. In Europe, many alchemists sought the philosopher's stone, and it was thought that such an unusual material as phosphorus might lead to the long-sought goal. It is of interest to note that Gottfried Leibniz, the German mathematician, then librarian for Duke Johann Friedrich at Hanover, arranged a contract between Brand and the duke, under which Brand was to demonstrate his process and reveal his method.

It is easy to understand the widespread interest that was aroused in the 17th century by the discovery of such a remarkable substance as phosphorus. A substance which glowed in the dark and took fire spontaneously upon exposure to the air was something startlingly new and mysterious. It is indeed notable that an element so difficult to isolate should have been discovered through the unguided fumbling of an alchemist.

In the decades that followed 1680, methods for the preparation of phosphorus from various animal and vegetable materials were developed and, in some instances, published. It was not until 1775, more than a hundred years after Brand's discovery, that Carl Scheele published the much easier method of preparing the element from bones, which then became the chief raw material used as a source of phosphorus.

The Phosphorus Atom.—The chemical atomic weight of phosphorus is 30.9738, and its atomic number of 15 indicates that there are 15 positive charges on the nucleus of the atom. Since the atomic mass number is 31, the nucleus is composed of 15 protons and 16 neutrons. The 15 electrons which revolve about the nucleus are arranged at three major quantum levels, usually referred to as the K-shell, the L-shell and the M-shell. There are two electrons at the first quantum level or K-shell, eight electrons in the L-shell, and five electrons in the M-shell.

In the nomenclature commonly used, the arrangement of the electrons about the nucleus of the phosphorus atom may be expressed as 1 s^2, 2 s^2 p^6, 3 s^2 p^3. In this expression the 1, 2, 3 refer to the major quantum levels or shells, the s and p to sublevels within the principal quantum levels, and the exponentially written numbers refer to the numbers of electrons at each sublevel.

The only stable isotope of phosphorus is P^{31}. Six unstable, radioactive isotopes have been produced: P^{28}, half life 0.28 sec.; P^{29}, half life 4.5 sec.; P^{30}, half life 2.5 min.; P^{32}, half life 14.3 days; P^{33}, half life 25 days; and P^{34}, half life 12.4 sec. Of these, only P^{32} is useful as a tracer element. Because of the important role that phosphorus compounds play in the chemistry of organic life, it is unfortunate that the only useful radioactive isotope has so short a half life in relation to the normal life cycle of higher plants and animals.

Occurrence.—Phosphorus does not occur free in nature, but its compounds are widely distributed and are found in many rocks and minerals. It ranks 11th in abundance in the lithosphere, of which the average content of phosphorus is about 0.12%. Some of the common minerals of phosphorus are apatite [$Ca_{10}F_2(PO_4)_6$], wavellite [$Al_6(PO_4)_4(OH)_6.9H_2O$] and vivianite [$Fe_3(PO_4)_2.8H_2O$].

Large deposits of rock phosphate are found in many localities. These deposits are of great economic value as a source of phosphate in the manufacture of fertilizers. In the United States the deposits of Florida and Tennessee have been exploited extensively, and exploitation of the deposits of Utah, Wyoming, Idaho and Montana is increasing rapidly. In Africa the deposits of Algeria, Tunisia and Egypt are also mined on a large scale. All these deposits were laid on the floor of shallow seas and are mostly the remains of myriads of aquatic microorganisms. The phosphate beds of the western United States are primary deposits which lie conformably with the shales, limestones and other formations of the region, whereas the main deposits of Florida, Tennessee and North Africa are secondary, being the residues from the leaching of phosphatic limestone. (*See* also MINERAL PHOSPHATES.)

Many textbooks of chemistry and technical articles erroneously refer to rock phosphate as tricalcium phosphate, $Ca_3(PO_4)_2$, although the phosphatic material present is actually a calcium fluorphosphate, or possibly hydroxyfluorphosphate, which gives the same X-ray pattern as the mineral apatite.

Phosphorus is one of about 20 elements essential to the growth, development, and maintenance of plants and animals, and the supply of phosphoric compounds in agricultural soils must be maintained. Where crops are removed, the supply of phosphorus compounds in the soil may become the limiting factor in crop production. Large quantities of phosphorus compounds are used as a fertilizer and an extensive deposit of rock phosphate therefore represents a great natural resource. (*See* also BIOLOGY: *Properties of Living Matter;* FERTILIZERS AND MANURES: *Phosphorus-Supplying Fertilizers.*)

Preparation.—Phosphorus may be prepared readily by heating metaphosphoric acid with carbon, or by heating a calcium phosphate with carbon and sand. Carbon monoxide and phosphorus vapour are evolved in both processes.

In the modern industrial method for the production of phosphorus, rock phosphate, coke and silica pebble are charged continuously into a three-phase electric furnace. The electric energy serves only to heat the charge, which melts and reacts chemically with the coke and silica to produce phosphorus vapour and carbon monoxide which pass out of the furnace, while a molten calcium silicate slag accumulates in the furnace. Any iron compounds present as impurities in the furnace charge are reduced and the molten metallic iron then absorbs phosphorus to form ferrophosphorus which is heavier than the slag and therefore sinks to the floor of the furnace.

From time to time the furnace is tapped and the ferrophosphorus is cast into pigs, while the slag is granulated by means of jets of water. The granulated slag is composed chiefly of calcium silicate. The ferrophosphorus is used in making iron alloys but the market does not utilize all the by-product ferrophosphorus produced. Several methods were developed for the recovery of the valuable phosphorus from the ferrophosphorus but none was in commercial use early in the second half of the 20th century.

The stream of gas from the electric furnace consists principally of phosphorus vapour and carbon monoxide. After the gas is freed of dust and then cooled the phosphorus condenses to the liquid and eventually to the solid form. Because it ignites spontaneously when exposed to air, the usual practice is to store the phosphorus under water.

Physical Properties.—Phosphorus exists in several allotropic forms which will be discussed later. The ordinary variety, when pure, is a colourless, semitransparent, waxy solid at room temperature, but is usually slightly yellow because of impurities present.

Although virtually insoluble in water, white phosphorus is slightly soluble in many organic liquids, in phosphorus trichloride, liquefied ammonia, and liquefied sulfur dioxide, and is extremely soluble in carbon disulfide. Its molecular weight in solvents, and in the vapour state, corresponds to a P_4 molecule. The atoms in the molecule are in a tetrahedral arrangement, the edge of the tetrahedron being 2.21 angstrom units.

When phosphorus vapour is heated, the dissociation of P_4 molecules into P_2 molecules becomes measurable at about 800° C. Spectrographic examination of hot phosphorus vapour indicates that P_4, P_2 and P molecules are present, but even at 1,200° C. the proportion of monatomic molecules is exceedingly small.

Some of the other physical properties of white phosphorus are given in the following table:

Specific gravity	1.83
Melting point	44.14° C. at 1 atm.
Boiling point	280.5° C. at 1 atm.
Heat of fusion	630 cal. ± 2 cal. per P_4 mol.
Critical temperature	720.6° C.
Heat of sublimation	14,066 cal. per P_4 mol.
Hardness	0.5 on Mohs' scale
Atomic heat capacity	5.69 cal. per gram atom
Atomic volume	16.9 c.c. per gram atom
Surface tension	43.09 at 78.3° C. 35.56 at 132.1° C.
Index of refraction	1.8244 for the D line at 29.2° C.
Parachor	37.7
Entropy $S°298$ (solid)	9.80 ± 0.02 cal. per gram atom per °C.
C_p, cal./mole P_4/° C., vapour	$= 19.25 + 0.510 \times 10^{-3}T - 2.980 \times 10^{5}T^{-2}$

Allotropic Forms.—The data accumulated from the many investigations of the allotropic forms of phosphorus are voluminous, confusing and contradictory. In the present summary the statements are those for which the experimental evidence seems most consistent and convincing.

White phosphorus exists in at least two allotropic forms. The one that occurs under ordinary conditions of temperature and pressure is called the α form. It has a density of 1.83. At −77.8° C. the α form changes to a β form which has a density of 1.88. The crystal habit of the α form is cubic whereas that of the β form is hexagonal.

The β form is strongly doubly refractive and this makes it possible to observe the transition from the one form to the other by means of a polarizing microscope.

Red phosphorus can be prepared by heating the white variety at 250° to 300° C. in a closed container. The conversion is accelerated by a trace of iodine. Red phosphorus may be obtained also by exposure of phosphorus vapour to an electric glow discharge, to a spark discharge, or to a heated tungsten filament.

Red phosphorus does not ignite in air at ordinary temperature and is not dissolved by the usual solvents for white phosphorus. The red form melts in the range 590° to 600° C. and, as ordinarily prepared, is amorphous or microcrystalline. Its colour, density and other physical properties, as well as its chemical activity, are governed by the conditions under which it is formed. Upon prolonged heating, the ordinary amorphous form of red phosphorus undergoes progressive, exothermic, irreversible transitions to crystalline modifications. Thermal analyses, X-ray diffraction measurements and microscopic observations lead to the conclusion that there are certainly three and possibly five forms of red phosphorus. At one end of this series of transitional forms stands the variety obtained by the methods ordinarily used for the conversion of white phosphorus to the red form. The density of that variety may be as low as 1.9, and its X-ray pattern is diffuse, which establishes the absence of structural regularity. As the change progresses from one form to the next, the X-ray pattern sharpens and becomes progressively more complex. The most highly crystalline modification obtained by the thermal aging of ordinary red phosphorus is probably at least monoclinic but the symmetry is usually distorted so that its optical properties are those of a triclinic crystal. This form has been called violet or metallic phosphorus. It seems best, however, not to increase the confusion with regard to red phosphorus by giving special names to any of the modifications.

Black phosphorus is deemed another distinct allotropic form of phosphorus and is obtained by subjecting white phosphorus to a pressure of 35,000 atmospheres at ordinary temperature or to 12,000 atmospheres at 200° C. This allotropic form is a flaky, crystalline material that resembles graphite and has a density of 2.699. It is a conductor of electricity with a resistivity of 0.711 ohms per centimetre cube, and is not dissolved by any of the liq-

uids that dissolve white phosphorus. Black phosphorus changes irreversibly into the red allotrope at about 550° C. under ordinary pressure.

Chemical Properties.—Phosphorus is a nonmetallic element and belongs in Group V of the periodic table. The subgroup to which it belongs includes the elements nitrogen, phosphorus, arsenic, antimony and bismuth. The transition from nonmetallic to metallic elements as atomic weights increase is unusually sharp in this subgroup. It is also characteristic of the subgroup that corresponding compounds of the five elements do not resemble each other as closely as might be expected, even when the formulas are alike. Probability of resemblance is greatest in the hydrides, less in the halides, and least in the oxides. Even in the hydrides, however, the correlation of properties for corresponding formulas is poor.

The usual valencies of phosphorus are three and five. It would be expected from the arrangement of electrons in the phosphorus atom that the valency due to exchange of electrons would be plus five when the outer shell is stripped of electrons, and minus three when the outer shell is filled by the capture of three electrons. The chemistry of phosphorus is complex, however, and the element forms many compounds wherein its valency is other than the simple kind due to loss or gain of electrons in the outer shell of the atom.

White phosphorus is relatively active. It glows in the dark and ignites spontaneously to form dense white fumes of the oxide P_4O_{10}.

It precipitates copper and lead from their solutions at ordinary temperatures and reacts with most metals to form phosphides at elevated temperatures.

Hydrides.—There are two well-known hydrides of phosphorus, namely PH_3 and P_2H_4. Phosphine, PH_3, is a colourless, poisonous gas of characteristic odour. It can be produced by heating white phosphorus in a solution of potassium hydroxide, or by the hydrolysis of a solid phosphide such as Ca_3P_2. Phosphine solidifies at −134° C. under its own vapour pressure of 27.3 mm., and there are at least four allotropic forms of the solid.

The hydrogen atoms of the phosphine molecule are replaceable by metals with the formation of unstable compounds such as PH_2K, PK_3, etc.

The hydride P_2H_4 is a liquid which boils at 52° C., solidifies at −99° C. and ignites spontaneously. Other solid hydrides such as $P_{12}H_6$ and P_9H_3 have been reported, but X-ray studies of these solids indicate that they are probably solid solutions of PH_3 in phosphorus.

The monovalent phosphonium radical PH_4^+ is analogous to, although much less stable than, the ammonium radical NH_4^+. Phosphonium iodide is a colourless, crystalline solid formed by the interaction of phosphine and hydrogen iodide; the corresponding chloride and bromide are gases.

Halides and Oxyhalides.—The halogen compounds of phosphorus are numerous. In addition to simple halides such as PCl_3 and PCl_5, there are many mixed halides such as $PFCl_2$, PF_3Cl_2, etc. Theoretically there are 20 simple and mixed halides of trivalent phosphorus and 56 such halides of pentavalent phosphorus. In addition to these halides, not all of which have been prepared, there are phosphorus halides of the type P_2I_4 which is analogous to the hydride P_2H_4.

There are also many oxyhalides of phosphorus, of formulas POF_3, $POCl_3$, $POFCl_2$, etc.; and for each oxyhalide there exists the corresponding sulfohalide, such as PSF_3, $PSFCl_2$, etc.

Oxides.—The three best-known oxides are: P_4O_6, usually called phosphorus trioxide and expressed as P_2O_3; P_nO_{2n}, sometimes written as P_2O_4 and called phosphorus tetroxide; P_4O_{10}, nearly always written P_2O_5 and called phosphorus pentoxide.

In addition to these three oxides, existence of an oxide P_2O_6 is indicated by considerable evidence, and some doubtful evidence suggests the possibility of P_4O and P_2O.

The oxide P_4O_6, phosphorus trioxide, is a colourless, crystalline substance which melts at 23.8° C. and boils at 175.4° C. It forms phosphorous acid, H_3PO_3, in cold water and therefore may be said to be the acid anhydride of this acid, but it yields phosphorous, phosphine, phosphoric acid and other compounds when treated with hot water. The vapour density, the Raman spectrum and the electron diffraction pattern of phosphorus trioxide indicate P_4O_6 molecules and the molecular formula of the trioxide when dissolved in molten naphthalene is also P_4O_6.

Its heat of vaporization is 9,400 cal. per mole at the boiling point.

The oxide P_nO_{2n} is a lustrous, crystalline substance of density 2.537 at 22.6° C. The vapour at 1,400° C. has a density corresponding to molecules of P_7O_{14}. Phosphorus tetroxide reacts slowly in water with some evolution of phosphine but the principal products are phosphorous acid and metaphosphoric acid, $(HPO_3)_n$.

The oxide P_4O_{10}, usually expressed as P_2O_5 and designated phosphorus pentoxide, is the main product obtained when phosphorus is burned in an excess of air. The vapour density, Raman spectrum and electron diffraction pattern agree in indicating a P_4O_{10} molecule of the T_d point group with a symmetry number of 12. This oxide exists in several forms which vary in appearance. The white, amorphous powder is the one most common but there is a vitreous, glasslike form and also a silky white form. The most volatile is a crystalline variety obtained by the sublimation of the ordinary white form *in vacuo*. The vapour pressure of this crystalline variety is one atmosphere at about 358° C.

Phosphorus pentoxide, P_4O_{10}, is an unusually effective agent for the drying of air. It hydrolyzes first to metaphosphoric acid. The water vapour pressure over this P_4O_{10}-acid mixture is not more than 10^{-5} mm. of mercury at room temperature. Its capacity for water absorption is low, however, since one gram of water will convert nearly eight grams of P_4O_{10} to metaphosphoric acid.

Sulfides.—The sulfides of phosphorus are not as closely analogous to the oxides as is usually the case with elements other than phosphorus. The sulfides P_4S_3, P_4S_5, P_4S_7 and P_4S_{10} are well known and there is some evidence for the existence of P_2S_5.

The Oxyacids of Phosphorus.—There are six well-known oxyacids of phosphorus, namely: hypophosphorous acid, H_3PO_2; phosphorous acid, H_3PO_3; hypophosphoric acid, $H_4P_2O_6$; metaphosphoric acid, $(HPO_3)_n$; orthophosphoric acid, H_3PO_4; and pyrophosphoric acid, $H_4P_2O_7$.

The barium salt of hypophosphorous acid can be formed through the prolonged boiling of phosphorus with an excess of barium hydroxide. The over-all equation is:

$$8P + 3Ba(OH)_2 + 6H_2O \rightarrow 2PH_3 + 3Ba(H_2PO_2)_2$$

The excess of $Ba(OH)_2$ is precipitated by means of CO_2 and the resultant $BaCO_3$ filtered off. Sulfuric acid then is added to the solution to free the hypophosphorous acid and to precipitate barium sulfate which then is removed. When the solution is evaporated, colourless crystals of hypophosphorous acid, H_3PO_2, appear. The acid is monobasic, and the Raman spectrum indicates that two of the hydrogen atoms in the molecule are linked directly to the phosphorus atom while the third hydrogen is in a P-O-H linkage. As written for organic acids, the formula would be H_2POOH. The acid and its salts are powerful reducing agents although they often react slowly.

Phosphorous acid, H_3PO_3, is a colourless, deliquescent solid which melts at about 72° C. It is a dibasic acid and is a strong reducing agent. It is prepared easily by drawing a stream of air through PCl_3 and then through cold water. The equation is:

$$PCl_3 + 3H_2O \rightarrow H_3PO_3 + 3HCl$$

Hypophosphoric acid, $H_4P_2O_6$, is formed by the slow oxidation of moist phosphorus under special conditions. Although the formula may be written as $P_4O_6.2H_2O$, the acid is not formed when P_4O_6 is brought into contact with water. The dihydrogen, disodium salt, $Na_2H_2P_2O_6.6H_2O$, can be prepared through the slow addition of red phosphorus to a cooled, alkaline solution of sodium hypochlorite. Hypophosphoric acid is a colourless, deliquescent solid which decomposes when heated. It is a tetrabasic acid, with one, two, three or four replaceable hydrogens.

Theoretically, metaphosphoric, pyrophosphoric and orthophosphoric acids can each be obtained by the reaction of P_4O_{10} vapour with the appropriate amount of water; *i.e.*,

$P_4O_{10} + 2H_2O \rightarrow$ metaphosphoric acid
$P_4O_{10} + 4H_2O \rightarrow$ pyrophosphoric acid
$P_4O_{10} + 6H_2O \rightarrow$ orthophosphoric acid

Likewise, orthophosphoric acid can theoretically be dehydrated to pyrophosphoric and to metaphosphoric acid in succession. However, phosphoric acids with compositions corresponding to these acids are not pure, simple acids, but are complex mixtures of several polymeric acids, the proportions of which depend upon the over-all concentration.

Metaphosphoric acid exists in several polymerized forms indicated by the general formula $(HPO_3)_n$. The salts of several of what were supposed to be the individual polymers are known by such names as Pascal's salt, Madrell's salt, Knorre's salt, Graham's salt, Kurrol's salt, etc. It has been found, however, that these supposed salts of individual polymers of metaphosphoric acid are mixtures of different complex polymers, the degrees of complexity of which have not been determined with certainty. The sodium salt of so-called hexametaphosphoric acid is formed by the heating of NaH_2PO_4 and is important industrially for the treatment of boiler feed water. In hard water this complex sodium phosphate forms soluble complexes with calcium ions and thereby prevents the formation of the usual insoluble calcium compounds responsible for boiler scale.

Pyrophosphoric acid, $H_4P_2O_7$, is a colourless solid. It is tetrabasic and, so far as the first replaceable hydrogen is involved, is a stronger acid than orthophosphoric acid. In aqueous solution it hydrolyzes slowly to orthophosphoric acid.

Orthophosphoric acid, H_3PO_4, is commercially the most important of the oxyacids of phosphorus. The acid and many of its salts find extensive industrial applications. Some of the most widely used salts of both metaphosphoric and pyrophosphoric acid are prepared most readily through dehydration of the appropriate orthophosphoric salt. Thus when the monosodium, dihydrogen salt of orthophosphoric acid is heated, sodium metaphosphate is formed:

$$n NaH_2PO_4 \rightarrow (NaPO_3)_n + nH_2O$$

And, likewise, when the disodium, monohydrogen salt of orthophosphoric acid is heated, the corresponding sodium pyrophosphate is formed:

$$2Na_2HPO_4 \rightarrow Na_4P_2O_7 + H_2O$$

Orthophosphoric acid is a tribasic acid and at ordinary temperatures anhydrous H_3PO_4 is a colourless, crystalline solid which melts at 42.3° C. to a syrupy liquid. It forms a hemihydrate $2H_3PO_4.H_2O$, which melts at 29.3° C.

Two methods are in common use for the manufacture of orthophosphoric acid. In the older method, rock phosphate is treated with sulfuric acid solution and the engendered calcium sulfate and other insoluble material filtered off. The impure solution of orthophosphoric acid can then be purified and concentrated. Because of the difficulties encountered in the removal of impurities and in the step of concentration, the phosphoric acid obtained by this so-called "wet method" is utilized almost exclusively in the manufacture of fertilizer superphosphate, for which purpose the impurities need not be removed from the acid. The modern method for the manufacture of orthophosphoric acid consists in the burning of white phosphorus in an excess of air to form P_4O_{10} which is cooled and the vapour hydrated to orthophosphoric acid mist, which is collected by means of an electrostatic precipitator. Acid of any desired concentration can be prepared by this method. The usual product contains about 80% H_3PO_4 and is relatively free from impurities. As produced in industrial plants the acid usually carries some solid impurities in suspension and traces of dissolved impurities, the most objectionable of which is hydrogen fluoride. The suspension can be removed by filtration or settling, and most of the hydrogen fluoride by blowing air through the acid.

It will be noted that in the case of several of the oxyacids discussed above, not all of the hydrogen atoms that appear in the formula are replaceable by metals. Inasmuch as the most common co-ordination number of phosphorus is 4, it is instructive to consider the following co-ordination formulas:

$[PO_4]H_3$; $[P\overset{O_2}{H}]H_2$; $[P\overset{O_2}{H_2}]H$; $[P\overset{O}{H^3}]$; $[PH_4]X$

These formulas lead to the expectation that the hydrogens replaceable by a basic element would be three in the case of the orthophosphoric acid molecule, two in the case of the phosphorous acid molecule, and one in the case of the hypophosphorous acid molecule. The co-ordination formulas are in agreement with the observed facts in each case.

The fourth member in the above-listed series is known only through its organic derivatives and the fifth member is represented in phosphonium compounds.

Two other oxyacids of phosphorus have been described in technical writing, namely permonophosphoric acid, H_3PO_5, and perdiphosphoric acid, $H_4P_2O_8$. It is known that a double oxygen (peroxide) group can replace one of the co-ordination elements. Thus, permonophosphoric acid would be:

$$\left[P\overset{O\text{-}O}{O_3}\right]H_3$$

and perdiphosphoric acid would be $H_2[O_3\ P\ O\text{-}O\ PO_3]H_2$.

The oxide P_4O_{10} is miscible with water in all proportions. Orthophosphoric acid contains 72.4% of P_4O_{10} equivalent, pyrophosphoric acid contains 79.8%, and metaphosphoric acid contains 88.75%. Compositions corresponding to these acids are solids under ordinary conditions. Compositions containing 75% to 76% of P_4O_{10} equivalent are liquid at room temperature. With small shift of the P_4O_{10} equivalent in either direction, solutions are obtained which will yield crystals when seeded at room temperature.

In the absence of seed crystals, however, the solutions can be strongly supercooled. Little is known about melting points in the composition range between pyrophosphoric and metaphosphoric acids.

Some Industrial Uses of Phosphorus and Its Compounds.—White phosphorus, as such, has but few industrial uses. In warfare it is used in incendiary bombs and for the generation of smoke screens. (*See* also INCENDIARY MIXTURES: *Phosphorus.*) Red phosphorus finds its main use in the match industry, as does the sulfide P_4S_5. (*See* also MATCH.)

The trichloride and the pentachloride of phosphorus are employed in the manufacture of organic chemicals.

Phosphorus pentoxide, P_4O_{10}, is used widely as a drying reagent in laboratories, but the oxide costs too much to permit its use for this purpose in industry.

Of the several oxyacids of phosphorus the one most widely used as such is orthophosphoric acid. This acid is used in dental cements, in the preparation of albumin derivatives, in the sugar and textile industries, and it serves as a substitute for the more costly tartaric and citric acids in the manufacture of food products such as jellies and essences.

Phosphoric acids are used as reactants in the manufacture of a large variety of phosphates of industrial importance. Of the sodium salts, the tripolyphosphate, $Na_5P_3O_{10}$, is used in the largest amounts.

Several other sodium salts also find wide uses.

When ground rock phosphate is treated with phosphoric acid a fertilizer known as superphosphate (sometimes called double or treble or triple superphosphate) is formed. The main reaction involved is indicated by the equation:

$$Ca_{10}F_2(PO_4)_6 + 12H_3PO_4 \rightarrow 9CaH_4(PO_4)_2 + CaF_2$$

Monocalcium phosphate, $CaH_4(PO_4)_2$, has a P_4O_{10} (or P_2O_5) equivalent of more than 60% but the concentrated superphosphate made from ground rock phosphate carries only 48% to 50% of P_4O_{10} equivalent. Hundreds of thousands of tons of this superphosphate are made annually, but several million tons of a much lower grade superphosphate are made annually through the acidulation of ground rock phosphate with sulfuric acid according to the equation:

$$Ca_{10}F_2(PO_4)_6 + 6H_2SO_4 \rightarrow 3CaH_4(PO_4)_2 + 6CaSO_4 + CaF_2$$

In this case the generated calcium sulfate is a diluent and the superphosphate made by this process contains 16% to 20% of P_4O_{10} equivalent.

Considerable tonnages of other phosphates such as $(NH_4)H_2PO_4$ and $(NH_4)_2HPO_4$ are also used in the fertilizer industry. The Tennessee Valley authority developed a process for the manufacture of a calcium metaphosphate fertilizer by the direct reaction between rock phosphate and P_4O_{10} vapour at about 1,100° C. This fertilizer carries 60% to 62% of P_4O_{10} equivalent.

Several of the phosphates of sodium, notably the so-called hexametaphosphate, tetrasodium pyrophosphate, $Na_4P_2O_7$, and trisodium phosphate, Na_3PO_4, are useful as water softeners. Disodium pyrophosphate, $Na_2H_2P_2O_7$, is used in electroplating baths and in tinning. Dicalcium orthophosphate, $Ca_2H_2(PO_4)_2$ (or $CaHPO_4$), is used as a supplement to animal and poultry food. It is also an excellent fertilizer but costs more than superphosphate upon the basis of P_4O_{10} equivalence.

Besides such inorganic phosphates as those mentioned above, several organic phosphates have industrial importance.

(H. A. Cs.)

PHOTIUS (*c.* 820–891), patriarch of Constantinople (858–867 and 877–886) who defended the autonomous traditions of his church against Rome and was the leading figure of the 9th-century Byzantine renascence. An accomplished scholar, Photius began his career as professor of philosophy at the Imperial Academy, to which he was appointed by Theoctistus, chief minister of the empress Theodora, reigning in the name of her son, Michael III. The marriage of his brother Sergius to Theodora's sister Irene gave him an entrée to the court. He became director of the imperial chancellery and a senator. In 855 he took part in an embassy sent to the caliph al-Mutawakkil. During his absence Theodora's brother Bardas murdered Theoctistus, deposed Theodora, and made himself regent. In the strife between the intransigent elements supporting Theodora and the liberals led by Bardas, the patriarch Ignatius became involved in a conflict with the government and was induced to resign. Photius, still a layman, was elected in his place, ordained within six days, and acknowledged by all the bishops (December 858). Soon afterward the intransigents refused him obedience and, during demonstrations provoked by them, Bardas, taking sharp measures, imprisoned Ignatius, whose patriarchate and ordinations were declared illegitimate. This judgment was confirmed by the papal legates sent by Pope Nicholas I in 861 on the ground that Ignatius had not been canonically elected but appointed by the empress. Nicholas himself, however, sided with the intransigent refugee monks who claimed to represent the patriarch Ignatius, disavowed his legates, and excommunicated Photius (863). The emperor Michael III retaliated with a violent protest in 865.

When Roman missionaries replaced Byzantine priests in Bulgaria, Photius convoked a synod (867) and condemned the violation of the rights of his church by Rome; Michael asked the Western emperor Louis II to depose Pope Nicholas. However, the co-emperor Basil, murderer of Bardas, assassinated Michael III, became sole emperor, and, in order to win the support of the intransigents, reinstated Ignatius as patriarch (Nov. 23, 867). The council of 869–870 confirmed the deposition and excommunication of Photius, but the majority of the clergy remained faithful to him and the emperor recalled him from exile. Photius became reconciled with Ignatius, who asked Pope John VIII to send legates to a new council. Ignatius died in 877 before the legates arrived. The council of 879–880 confirmed Photius as patriarch and canceled all conciliar measures against him. Photius canonized Ignatius. Photius had to resign in 886 at the instigation of Leo VI (who succeeded Basil in that year), and died in the monastery of Gordon, probably on Feb. 6, 891, in communion with Rome. He had contributed to the healing of the rupture which his firm attitude and the intrigues of the intransigents had provoked; and he had extended Byzantine religious influence to Bulgaria, Moravia, and Russia. He was canonized probably at the end of the 10th century, and his feast day is Feb. 6.

Photius' most important work is the *Bibliotheca* or *Myriobiblion*, giving criticism of and extracts from 280 works which he had studied. Thanks to this immense achievement, much is known of many Greek writers, pagan as well as Christian, whose works have perished. A manuscript of his *Lexicon*, found in 1959 in the monastery of Zabora in northern Greece, completes the manuscript at Trinity College, Cambridge. Photius appears also to have taken part in the composition of the *Etymologicum genuinum*. His *Amphilochia* gives answers to about 300 questions on religion. He also wrote epistles, homilies, and other theological works, including a treatise against the Manichaeans, the *Mystagogia* (on the procession of the Holy Spirit), and commentaries on the New Testament extant in fragments only.

(F. Dv.)

PHOTOCHEMISTRY is the study of chemical processes initiated by light or, more generally, by electromagnetic radiation. For a photochemical process to occur, energy in the form of visible, infrared, or ultraviolet radiation must be absorbed by a substance. The immediate consequence of this absorption is called the primary photochemical process. Any subsequent changes following from this process are called secondary processes, and are also included within the domain of photochemistry. The process by which a photochemical reaction is carried on is called photolysis.

The theoretical aspects of photochemistry are derived largely from the principles of atomic and molecular physics and of quantum mechanics, while its analytical methods are mainly those of spectroscopy. The reader therefore may have occasion, throughout, to consult the articles ATOM; LIGHT; MOLECULAR SPECTRA; QUANTUM MECHANICS; and SPECTROSCOPY. More particular cross references are provided in the text.

Scope.—Photochemistry differs from most other aspects of chemistry in one regard. If an atom or molecule absorbs energy from a beam of light, it gains far more energy than it ever could by other methods; *e.g.*, from ordinary heating. Consequently photochemical processes are sometimes extremely efficient for the conversion of energy from light into chemical energy. The most important single photochemical process for living systems, photosynthesis, is exactly of this type. Through photosynthesis, green plants convert light energy very efficiently into stored chemical energy, producing carbohydrates from carbon dioxide and water. Many other natural phenomena are photochemical processes or are intimately linked to photochemical processes. The ozone in the upper atmosphere, which shuts out most of the intense ultraviolet radiation from the sun, is produced by the action of light on oxygen molecules: sunlight breaks some of the molecules into atoms, and these combine with other oxygen molecules to make ozone.

Bleaching laundry in sunlight is at least partly a photochemical process and so is the darkening of white lithopone (zinc sulfide) paint. Photography is based on a photochemical process, the action of light on grains of silver chloride or silver bromide. This is a process in which conventional chemical action (development of the film) amplifies the photochemical action of light alone, converting to metallic silver only the grains of silver salt which have absorbed minute amounts of light.

(For further examples of the scope of photochemistry see *Applications*, below.)

Kinds of Photochemical Effects.—The action of light on a chemical system may take various forms:

1. Light may act as a booster to maintain a reaction which might otherwise proceed at an imperceptibly slow rate and in which the reacting molecules exchange little or no net energy with their environment. Some molecular rearrangements (isomerizations) fall

into this category (*see* ISOMERISM; MOLECULAR REARRANGEMENTS).

2. It may act as a trigger, initiating a reaction that, once started, can proceed spontaneously. An example is the initiation of the reaction between hydrogen (H_2) and chlorine (Cl_2) to give hydrochloric acid (HCl). Hydrogen and chlorine can be kept mixed together for an indefinite period at room temperature in a dark container, but if violet or ultraviolet light reaches the mixture the two substances react explosively, giving off considerable stored chemical energy as heat. The primary photochemical process in this case is the formation of two chlorine atoms from a Cl_2 molecule.

3. In some photochemical processes, absorbed light converts the reacting molecules to a new state higher in energy than their initial state; in this case the energy of the absorbed light is converted into chemical potential energy and is stored that way. Most photochemical processes occurring in biological systems are of this type; *e.g.*, ultraviolet irradiation converts ergosterol, found in plant and animal tissues, into a biologically active substance, vitamin D.

4. A photochemical system may store light energy from the sun as chemical energy and then, only incidentally to the photochemical process, release that energy as electrical energy. This is the solar battery, used to supply the power in satellites and space vehicles.

All these processes have one common characteristic: each requires, at some stage, that a large quantity of energy be available to a single reacting atom or molecule. The requirement may be a thermodynamic one, in which the products simply contain more stored energy than the reactants. Alternatively, the requirement may be kinetic; in this case the products may store more or less energy than the reactants, but some step along the reaction path requires a large quantity of energy to surmount a barrier, as it were. (The H_2-Cl_2 reaction has as its barrier the requirement that a Cl-Cl bond be broken to convert a chlorine molecule into its two constituent atoms.) In more complex molecules, the rearrangement from one shape to another exhibits an energy barrier because, between the initial and final structures, there must be a series of intermediate shapes of higher potential energy than either the initial or final shapes.

History.—The hydrogen-chlorine reaction (*see* above) was perhaps the first recognized photochemical reaction; it was observed by W. Cruikshank (1801) and studied in detail by J. W. Draper (1844). That only the absorbed light can affect a chemical reaction was recognized by T. von Grotthus (1818) and by Draper, but a century passed before this qualitative idea could be stated as a quantitative law. Between the era of Cruikshank, Grotthus, and Draper and the development of the modern theory by Einstein, photochemistry was largely confined to the identification of reaction products, often from the action of sunlight (work of A. Benrath; D. Berthelot; G. Ciamician and P. Silber; E. Paterno and G. Chieffi; and the early work of H. Stobbe and R. Stoermer).

The basic process by which light is absorbed by matter was first proposed by Albert Einstein (1905, 1912, 1916). His work was directed particularly toward the photoelectric effect (*see* PHOTOELECTRICITY) but the interpretation is general, and provides the foundation of modern photochemistry: a beam of light is a beam of photons, or quanta (energy packets) of electromagnetic radiation (see *Photochemical Quantities*, below). The energy of each photon is proportional to the frequency of the light, and the total number of photons is proportional to the intensity of the light. The primary photochemical process then follows directly from the absorption of one photon by one atom or molecule. (Exceptions may occur if the radiation field is very intense; then the concentration of photons may be so high that some molecules absorb two photons.)

After 1910 E. Warburg began his classic study of the formation of ozone (O_3) by the action of ultraviolet light on the normal oxygen molecule (O_2). This work represented the first measurement of the number of product molecules formed for each quantum of energy absorbed: the so-called quantum yield of the reaction (*see* below). In the next few years most of the foundations of modern photochemistry were completed. In 1921 O. Klein and S. Rosseland predicted "collisions of the second kind": collisions in which excess internal energy of an atom or molecule is exchanged with its collision partner or converted into kinetic energy of the colliding partners, or, from another viewpoint, collisions in which an excited atom or molecule is deactivated by energy exchange. Such collisions, involving the exchange of excitation between mercury and thallium, were observed by G. Cario and J. Franck (1922–23).

The role of chain reactions in photoprocesses was first elucidated for the H_2-Cl_2 reaction by M. Bodenstein and his co-workers in the period 1913–25, and the field grew steadily in the next three decades. From about 1955 photochemistry expanded rapidly as it came to be used as a tool for the synthesis of organic molecules, and was extended to the study of very short wavelengths (including X rays and gamma rays) and of chemical phenomena produced by the optical amplifier, or laser (*q.v.*).

THE PRIMARY PHOTOCHEMICAL PROCESS

Photochemical Quantities.—The most fundamental idea and the basis of all quantitative interpretations in photochemistry is the quantum-mechanical principle that all energy consists of packets called quanta, and that the quanta of electromagnetic radiation, called photons, act like particles. The energy E (in ergs) of each photon is related to the frequency of light, ν (in cycles per second) by the direct proportion $E = h\nu$. The constant of proportionality h is called, after its discoverer, Planck's constant; it has the value 6.67×10^{-27} erg-sec. Alternatively, since the frequency ν and the wavelength λ of light are related to c, its velocity (3×10^{10} cm. sec.) according to $\nu\lambda = c$, the energy of a quantum is related to the wavelength of the corresponding radiation by the inverse proportion $2 \times 10^{-8}/\lambda$ if E is in ergs and λ is in angstrom units; $E = \frac{hc}{\lambda}$, which is 12,400/λ, if E is in electron volts per photon and λ is in angstrom units; or $2.85 \times 10^5/\lambda$ if E is in kilocalories per mole of photons and λ is in angstrom units. The angstrom unit (Å) is 10^{-8} cm. and is commonly used to designate wavelength. The electron volt (ev), 1.602×10^{-12} ergs, is the usual unit for measuring energies of individual particles in atomic physics. The energy unit, the kilocalorie (kcal), is the standard chemical unit; chemical energies are usually given in terms of kcal/mole. The mole is Avogadro's number of particles, 6×10^{23}, so chosen because 6×10^{23} is the number of atomic mass units per gram. One mole of photons is often called an einstein.

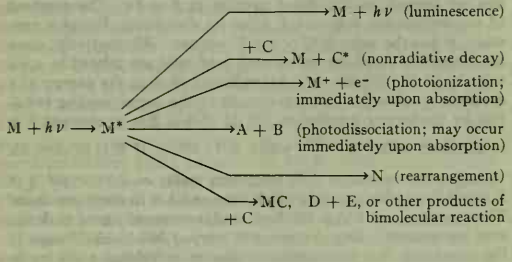
By means of these quantities we can express more precisely the relationship between ordinary chemistry and photochemistry, in terms of some simple magnitudes. Green light, for example, has a wavelength of about 5000 Å. (The entire visible region lies between about 4000 and 7000 Å.) Consequently a photon of green light has an energy of about 2.5 ev, or an einstein of green light photons has an energy of 57 kcal. Ultraviolet light of wavelength 2500 Å has just twice as much energy per photon or per mole. By comparison, a weak chemical bond requires an energy of about 1 ev to be broken, while a very strong bond requires over 10 ev. At the other end of the scale of comparison, two molecules colliding at room temperature strike each other with an energy of only about 0.05 ev.

Absorption Phenomena.—The history of a photochemical reaction necessarily begins with the absorption of a quantum of electromagnetic energy by an atom or molecule. Initially, the absorber is in a state in which its energy is relatively low. The energy contained in the absorber is essentially of four types: (1) kinetic energy of motion through space (translational energy); (2) energy of rotational motion about its centre of mass; (3) energy of vibration of the component atoms against each other, if the species is a molecule; and (4) energy of the negatively-charged electrons moving in the field of force produced by the other electrons and the positively-charged nuclei. The energy change initiating a photochemical process virtually always involves excitation of one electron from a state of low energy to a state of higher energy. When the absorber is a molecule, changes in rotational and vibrational energy usually occur also; the translational energy of an

atom or molecule is almost completely unaffected when a quantum of radiation is absorbed except in the case of gamma radiation.

Usually, in the initial low-energy state of an absorber, the electrons are in their lowest possible state of energy, or quantum state. The electrons cannot absorb all incident radiation; they can only absorb quanta whose energy corresponds to the allowed quantum jump for that particular absorber. (A hydrogen atom in its lowest state can absorb only those quanta whose energies fit the expression $13.7\ (n^2 - 1)/n^2$ ev, when n may equal 2, 3, . . . ; it cannot absorb a 6 ev photon, for example.) The energies that a quantum may have in order to be absorbed by a molecule or atom correspond to the characteristic frequencies of the absorption spectrum of that species. The spectrum of an atom consists of lines and, above a minimum energy characteristic of the element, a continuum. A molecular spectrum contains many more lines because of the many ways a molecule may absorb energy into vibrational and rotational motion; these lines generally are grouped into bands. Any molecule also has a continuous spectrum.

The occurrence of a photochemical reaction, then, begins with the absorption of a quantum whose energy corresponds to a characteristic absorption line or band of the species. Moreover the energy is used mainly or entirely to raise one electron into an excited state so that the molecule or atom is in an activated state. The primary photochemical process can be shown schematically, using the asterisk to designate an electronically excited species:

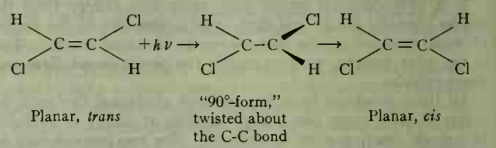


Each kind of molecule has its own spectrum, within which more than one kind of excitation usually is possible. One of the origins of continuous absorption is photoionization; in this case the excited state of the electron is one in which it is free to escape. It is the one case in which absorption and primary reaction are essentially identical. Photo-ionization can be thought of as a prototype —perhaps the most elementary photochemical process. Continuous absorption is characteristic of a transition in which a new free particle is produced: it may be an electron, as in photo-ionization, or it may be an atom or a molecular fragment. These latter two are produced by photodissociation, a second type of photochemical process, which usually occurs when the electron being excited moves away from a locale where it can participate in a chemical bond, into some other region where it is unable to use its attraction to pull two nuclei together. In normal photodissociation the excited electron remains bound to one or the other of the products of the photolysis. Photodissociation is sometimes almost as directly linked to the absorption process as photo-ionization is, but it can also be considerably slower.

Absorption in a line or band spectrum leaves all the particles bound together with their geometrical configuration of atoms essentially unchanged, at least for a short time (10^{-14} sec.). The change produced by such an absorption involves the excitation of one electron from a closely held low-energy state to a larger and more loosely bound excited state. In many cases there are two or more possible excited states and several electrons that could undergo a transition; however, since each spectral line or band corresponds to one specific electronic transition it is frequently possible for an experimenter to study one kind of electron excitation at a time. This can be done by irradiating the sample with light lying only in the energy range corresponding to the transition of interest. An experiment of this type can often be done with light of almost a single pure frequency (monochromatic light).

Subsequent States.—As soon as an electron is excited and a molecule is in an activated state, several things can follow. The molecule may return to its initial state, without reacting, in either of two ways: it may radiate, giving up a light quantum by luminescence (*q.v.*); or it may lose all its excitation energy, without radiating or reacting, by undergoing nonradiative decay, a process that requires effective collision partners to carry off the excitation energy. Nonradiative decay usually goes through two stages. In the first step, little or no energy is lost; the energy of electronic excitation is simply converted into vibrational energy by what is called intersystem crossing or internal conversion. In the second stage, the excess energy is given up to the environment gradually, through a succession of collisions.

If the excited molecule does react, it may do so in any of several ways. It may undergo photo-ionization or photodissociation. It may undergo an intramolecular reaction like a rearrangement, or it may undergo an intermolecular process. An example of rearrangement is the conversion of *trans*-1,2-dichloroethylene into its *cis* isomer:



The product, in this case, has almost the same energy as the starting compound; the excitation energy required to reach the twisted intermediate form must be given off somehow by the product, usually by collision.

Primary intermolecular reactions may involve nothing more than the transfer of a quantum of energy, as with mercury (Hg) and ethylene (C_2H_4):

$$\mathrm{Hg\ (vapour) + h\nu \longrightarrow Hg^*}$$
$$\mathrm{Hg^* + C_2H_4 \longrightarrow Hg + C_2H_4^*}$$

leaving the excited ethylene to undergo secondary reaction. The intermediate kind of primary nondissociative reaction uses collisions in a way akin to the nonradiative decay process. An excited molecule undergoes a collision which converts it into a new reactive state without removing much of its excitation energy. The collision may change the geometry of the reactive molecule into a form that can rearrange bonds or dissociate readily, or it may change the electronic state of the molecule through internal conversion or intersystem crossing. Changes in electronic state usually involve only the single excited electron, but sometimes the molecular geometry is also involved.

In order for any state, be it the initial excited state or any subsequent one, to play a part in a photochemical reaction, it must endure long enough for the reaction to occur. Each photochemical reaction competes with radiative and nonradiative de-excitation to consume the activated molecules. A few typical numerical examples will illustrate the way this competition goes on. Fast luminescence, called fluorescence, occurs with a half-life of about 10^{-8} sec.; *i.e.*, roughly half of the excited molecules in any sample will radiate their excitation energy away in about 10^{-8} sec. provided they have an allowed path for fluorescence and provided they are not destroyed faster by some other process. Simple dissociations of excited molecules occur much faster: an excited molecule in an unstable state dissociates in about the time it takes an atom to go through one vibrational period, or about 10^{-13} sec. Consequently a molecule excited to a truly dissociating state has virtually no chance to radiate and will indeed follow the path of dissociation. Other unimolecular processes may occur with characteristic times ranging from 10^{-13} sec. up to a few seconds, if no other process interferes.

Radiative processes can also be slow. Slow luminescence is called phosphorescence, and is the result of emission of a quantum from a molecule undergoing a relatively improbable ("forbidden") transition. Fluorescence is the result of an "allowed" transition. Phosphorescence frequently is characterized by a lifetime for the

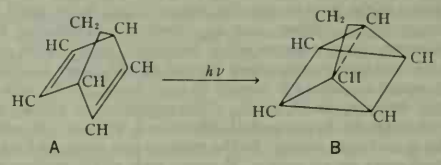
excited molecule between 10^{-5} and 10^{-2} sec., but many cases outside these bounds are known. Fluorescence, phosphorescence, dissociation, and some rearrangements involve only a single molecule and have specific rates (rate per unit of reactant concentration) or lifetimes for reactant molecules that are independent of the number of molecules present. Processes involving two molecules have specific rates that depend on the concentration of collision partners, since they depend on the frequency of collisions. The maximum rate for a bimolecular reaction is just the collision rate; this rate is attained only if the reaction occurs with every collision. The collision frequency for most molecules at a pressure of 1 atm. is above 10^9 per sec. so that the lifetime of a reactive species toward bimolecular reaction must be 10^{-10} sec. or more. Since collision frequencies increase directly in proportion to pressure, a bimolecular reaction rate can be increased or decreased over several orders of magnitude. The value of 10^9 per sec. at 1 atm. pressure corresponds to a reaction rate constant of about 2×10^{10} litres per mole-sec.; that is, the rate of reaction per unit of concentration of each species has an upper limit of about this figure. If one reactant is hydrogen, then the rate can be a bit higher simply because of the high velocity of the light hydrogen atoms or molecules.

In solution, the maximum bimolecular rate is governed by the rate at which the reactive species can diffuse together through the liquid or solid medium. This rate was derived by M. Smoluchowski and P. Debye, who showed that it is about 10^{10} litres/mole-sec. for solutions in water and other solvents of similar viscosity. Like the collision frequency, it represents an upper limit for the rate of reaction. Rates in solution are inversely proportional to the solvent viscosity so that bimolecular processes generally proceed slower in glycerin than in water, for example. Bimolecular de-excitation processes are usually limited by the rate at which the internal electronic state can change. This rate is as high as 5×10^8 litres/mole-sec. in rapid cases, and may be smaller by several powers of 10. Comparison of these various rates shows the following: (1) Dissociation will almost always occur if it is an available path. (Actually, in a solution, the dissociating species are sometimes trapped together by the surrounding solvent molecules and recombine with each other. This is the "cage effect" discovered by J. Franck and E. Rabinowitch.) (2) Fluorescence predominates over inefficient bimolecular reactions in the gas phase at atmospheric pressure, is quenched by efficient bimolecular reactions (those with a probability of reaction above 1 in 10, per collision), and is quenched in some cases by nonradiative decay. (3) Fluorescence and unimolecular reactions in solution are also likely to be slow compared with efficient bimolecular processes but are favoured by solvents of high viscosity. Again, fluorescence is sometimes less efficient than nonradiative decay, sometimes more efficient.

When a molecule changes its electronic state without direct absorption of light, as in nonradiative decay or internal conversion, it may go into a new excited state which, left alone, would be short-lived (less than about 10^{-6} sec.); or it may go into a long-lived (metastable) excited state. Both types are known in photochemistry, but the long-lived states are particularly important in storing energy for chemical processes. The most important of the last-named kind of transition is a single-triplet transition, or an intersystem crossing process.

Triplets are the most commonly found phosphorescing states. They cannot radiate rapidly, and are therefore among the most long-lived excited species. For this reason triplets are frequently the primary products of photochemical reactions. Excited singlets are sometimes found, but because of their shorter lifetimes, they are susceptible to decay processes, often to triplets. Triplets can be identified by their magnetic properties; by contrast with singlets, the individual electron magnets of a triplet do not compensate and cancel each other so that triplets exhibit weak magnetism (paramagnetism). This can be detected either by measuring the magnetic susceptibility of the material or by observing the reorientation of individual electron magnets in combined electric and magnetic fields (electron paramagnetic resonance). Triplets in irradiated naphthalene were first detected this way by C. A. Hutchinson and B. W. Mangum in 1958–61. (*See* MAGNETISM: *Paramagnetism.*)

An interesting case in which the entire photochemical process occurs in the primary reaction is that of valence tautomerism. The name is used for cases in which two molecular structures differ very little in the relative positions of their atoms, but have different arrangements of chemical bonds. One clear example is the photoisomerization of bicyclo [2,2,1]-heptadiene, or norbornadiene:

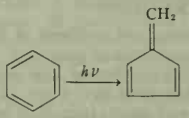


Structures A and B are nearly identical geometrically, yet represent different states of the electrons. Both are singlet states, but apparently B is stable and neither radiates nor decays nonradiatively to A.

SECONDARY PROCESSES

If an excited molecule does not return by a direct path to its lowest energy state, then it must dissociate, react with neighbours or itself, or revert to a new electronic state, still having some excitation energy. These are the primary steps. Any subsequent step is a secondary reaction. An example is Warburg's finding that when the oxygen molecule (O_2) absorbs light whose wavelength is shorter than 1750 Å, it becomes two oxygen atoms in the primary dissociation step; the only secondary reaction of importance in pure oxygen is then the reaction of oxygen atoms with O_2 to produce ozone (O_3).

Rearrangement Reactions.—These reactions, in which atoms move from one site to another within a molecule, may be interpreted as secondary reactions following the photoexcitation process. Benzene irradiated with light between 2000 Å and 3000 Å rearranges (inefficiently) to fulvene with the movement of a hydrogen atom:



In a case of this kind the first step involves only the excitation of one of the six relatively free electrons of the double-bond system of benzene. These six electrons are not strongly bonding, and especially do not participate in carbon-hydrogen bonds to any significant degree. Thus only in a secondary step following photoexcitation can the atoms rearrange to the molecular structure of the product.

Frequently the primary photochemical process is only used as a tool to permit the secondary reactions to be studied. Photosensitized reactions often fall into this category. Mercury atoms can absorb light from a mercury lamp very efficiently and then, in their excited state, collide with other molecules and transfer their excitation to these molecules. R. J. Cvetanovic (1955) used this technique to dissociate nitrous oxide (N_2O) to prepare and study oxygen atoms. The reaction sequence proceeds this way:

$$\mathrm{Hg} + h\nu \longrightarrow \mathrm{Hg}^*$$
$$\mathrm{Hg}^* + \mathrm{N_2O} \longrightarrow \mathrm{Hg} + \mathrm{N_2} + \mathrm{O}$$

(The alternative mode of decomposition, to give NO + N, does not seem to occur.) Then the oxygen atoms may react with whatever other species are present. Measuring the amount of nitrogen produced in a photolysis gives directly the number of oxygen atoms which were available for reaction. Many other sensitizers, both atomic and molecular, can absorb and then transfer energy the way mercury does; each has its characteristic energy.

Chain Reactions.—If a primary step involves dissociation of a molecule into two radicals, the secondary steps are often chain reactions (M. Bodenstein, 1913; W. Nernst, 1918; N. N. Semenov, 1930–43). J. A. Christiansen and H. A. Kramers (1923) developed the idea that there could be cycles in which reaction of an

active intermediate with a molecule of starting material to give product necessarily produces a new active intermediate. The hydrogen-chlorine reaction is an example. Light dissociates a few chlorine molecules into atoms, which then attack H_2 molecules to give HCl product and H atoms. The H atoms return to Cl_2 molecules to produce more HCl and Cl. Thus:

$$h\nu + Cl_2 \longrightarrow 2Cl$$
$$Cl + H_2 \longrightarrow HCl + H$$
$$H + Cl_2 \longrightarrow HCL + Cl$$

A reaction of this kind requires an initiator (light, in this case) and a propagating mechanism, and may involve a terminating step. Termination actually occurs either when the concentration of at least one reactant becomes very low, or when another substance, (*e.g.*, oxygen or iodine) is present to react more rapidly with the radicals than can the H_2 or Cl_2. The reaction must also be exothermic or nearly thermoneutral, otherwise it may cool the system so that it no longer reacts. In the reaction just cited, 44 kcal are given off every time 1 mole of H_2 and 1 mole of Cl_2 react to give 2 moles of HCl so that considerable heat is generated—usually much faster than it is radiated or transferred to the vessel walls, and an explosion is the result. A much more unstable situation arises if one radical initiator produces more than one new radical. This is the case in the reaction of oxygen with acetylene or of oxygen with hydrogen. In the latter case a branching chain can be initiated by the following mechanism:

$$H + O_2 \longrightarrow OH + O$$
$$O + H_2 \longrightarrow OH + H$$
$$OH + H_2 \longrightarrow H_2O + H$$

Other processes enter into the reaction but the key steps for chain branching are exemplified by the first two reactions above; the third is a normal chain-propagation step.

Chain reactions, normal and branching, always produce many product molecules for every quantum absorbed; *i.e.*, the quantum yield may be much greater than 1 for the reaction. Reactions involving no chain processes necessarily have quantum yields near or below 1, while a reaction like the H_2-Cl_2 reaction may reach a quantum yield of 80,000. Even a rough measurement of quantum yield will generally show whether a reaction proceeds through a chain mechanism.

EXPERIMENTAL METHODS

The methods of photochemistry arise from problems of three main kinds, in the following order of experimental procedure: (1) There is always the problem of getting the desired light energy into the system being studied. (2) One must have a way of determining the progress of the reaction—of getting immediate pertinent information from the experiment. (3) One must have the means of determining, from results of individual experiments, the broader inferences for which the study is carried out; *e.g.*, photochemists commonly try to determine from a series of individual reactions the mechanism of a reaction, on the detailed level of the behaviour of each atom throughout the progress of the reaction.

Illuminating the Sample.—This is largely a problem of devices. Light itself can be varied in four independent ways: (1) The frequency or energy of the light can be controlled. This determines the amount of energy given to each absorbing molecule or atom. (2) The intensity of the light can be varied, to control the rate at which photons arrive at the sample, and thereby to control the number of excited molecules present at one time. (3) The total illumination can be varied, to control the total number of excited molecules produced. (4) With the advent of lasers it became possible to control the coherence of the electromagnetic field; *i.e.*, to control the range over which the electric field of force of the light wave is really a sinusoidally oscillating force field. (*See* ELECTROMAGNETIC WAVES: *Maxwell's Field Theory.*)

In the earliest photochemical observations the white light of the sun was the source. No control could be exerted, of course, on the frequency of light coming from the source itself, but simple controls of the light received were available through the use of sample containers of differing composition; *e.g.*, heavy flint glass transmits very little ultraviolet radiation (to about 3600 Å), borosilicate (Pyrex) glass transmits light to a wavelength of about 3000 Å, and some fused silica is transparent to wavelengths shorter than 1700 Å. The next simplest way to control the wavelength reaching the sample is to interpose a suitable filter in the light path. Filters may transmit broad bands of frequencies or narrow and nearly monochromatic bands. A more complex step is the use of the monochromator, a device (usually a prism or diffraction grating) that permits the continuous variation of light frequency.

Incandescent sources like sunlight and ordinary electric tungsten-filament lamps emit light of all frequencies. The total intensity and the distribution of this intensity in any source depends primarily on the source temperature alone: intensity can only be increased if temperature is increased. Consequently the energy available for such sources is severely limited. For higher intensities it is often possible to use the emission spectrum of an atomic or molecular vapour. Some common sources use mercury, cadmium, sodium, xenon, hydrogen, or deuterium in an electric arc discharge to provide intense and steady fluxes of radiant energy. If the lamp pressures are low the atomic lines emitted by mercury, cadmium, or xenon are sharp and the lines from one element are well separated. It is easy to eliminate all the radiation from a mercury lamp except the one desired atomic line, thereby obtaining a choice of intense illumination at 1849 Å, 2536 Å, 3650 Å, 4046 Å, 4358 Å, or 5460 Å. If the pressure of the emitter is high, the emitted frequencies span a broad band and can be sorted with filters or a monochromator. Such lamps often deliver as much as 100 w. of power in just a few lines, broadened or not. (*See* also LIGHTING: *Modern Electrical Light Sources: Gaseous Vapour Lamps.*)

For very intense illumination, conventional steady arcs, discharge tubes, and incandescent sources are inadequate. If a very high flux of quanta is required, then a flash tube, a pulsed X-ray or gamma source, or a pulsed laser is required. The flash tube is a gas-filled tube, usually with a pressure of roughly 0.1 to 0.01 atm. of gas, to which a large amount of stored electrical energy is delivered in a very short time. Typically a medium-energy flash in an argon-filled tube might last 5×10^{-5} sec. and radiate 500 joules of energy as light, thereby emitting 10^7 w. (10 Mw.) of light energy. This energy is divided between continuous and line emission and is distributed over a very wide wavelength range, extending from the infrared to below 2000 Å in the ultraviolet. Pulsed X-ray sources deliver comparable amounts of energy, almost all of which is in the high-energy range; these sources characteristically achieve ionization of many molecules per absorbed photon. Pulsed electron sources, though not strictly photochemical, produce the same type of products as pulsed X-ray sources. The most intense monochromatic source is the pulsed laser, which can deliver as much as 10^8 w. of power for 10^{-8} sec. within a single spectral line. Within its range, the laser emits about 1,000 to 10,000 times the energy radiated by a flash in the same wavelength range, even though the total power delivered by both may be comparable.

Samples to be subjected to photochemical reaction may be gases, pure liquids, pure solids, or solutions. Gases must be used at low pressures to study unimolecular processes or such phenomena as the way the absorbed energy is eventually transmitted to the environment. In gases at high pressures or in condensed phases, the absorber is in intimate enough contact with its environment (or collides sufficiently often) that, apart from electronic excitation energy, it is in equilibrium with the environment. In condensed phases, therefore, electronically excited molecules have their best opportunity to be stabilized, by losing whatever excess vibrational energy they have before dissociation takes place. If the sample is in a solid, a pure or mixed crystal, or a glass, the molecules are not free to move through the medium or in many cases, even to rotate. Such an environment encourages reaction with nearest neighbours, intramolecular reaction, or simply stabilization of the primary products of the absorption process. Phosphorescence from triplet states, for example, is very commonly the result of irradiation of an organic substance in a glassy solution at −195.8° C, the normal boiling temperature of nitrogen.

Monitoring the Reaction.—The problem of monitoring the photochemical reaction may be solved by many physical and chemical methods. The experimenter simply suits the method to each

specific problem in turn. It is often sufficient just to know what the final reaction products are. Naturally this level of monitoring relies on all the methods of qualitative identification—often, particularly, on methods well suited for identifying small amounts of samples. Vapour chromatography, mass spectroscopy, and conventional spectroscopy (visible-ultraviolet electronic spectroscopy, infrared vibrational spectroscopy, electron paramagnetic resonance spectroscopy, and nuclear magnetic resonance spectroscopy) are powerful tools for these analyses. Furthermore, they can all be used at the next level of inquiry, the stage at which one asks for the relative amounts of each final product.

Often the information sought from a photochemical reaction can only be derived by examining the intermediates—the species present during the course of the reaction but not at the end. Sometimes an indirect observation identifies an intermediate; methyl (CH_3), ethyl (C_2H_5), and other radicals react with metal surfaces and can be detected by their ability to remove a metal mirror from a vessel's walls. Radical intermediates can also be detected if a "radical quencher" is added to the reacting mixture. Quenchers (*e.g.*, I_2, NO, sometimes O_2) react very rapidly with free radicals to form identifiable products. In their presence reactions involving radical intermediates usually do not go on past the stage of radical production because the quenching process consumes the radicals faster than does the reaction under study. Ionic intermediates can sometimes be inferred from the products that still appear even in the presence of radical scavengers.

More direct methods of studying the intermediates are available in many cases. If a reaction is made to go slowly enough the intermediates can sometimes be observed by conventional means. Many simple radicals can be detected in glassy solutions at low temperatures (below about −190° C). In this method, a hydrocarbon or hydrocarbon mixture is cooled enough to form a glass and then irradiated with high energy radiation, either X rays or gamma rays. Examination of the glass by electron paramagnetic resonance spectroscopy shows the presence of simple free radicals like ethyl or methyl, and usually gives enough information for their unambiguous identification.

Transition intermediates can be found and identified in some photochemical reactions proceeding at their natural rapid rates. One method of doing this is flash-kinetic spectroscopy, advanced first by R. G. W. Norrish and G. Porter (1949) and independently by G. Herzberg and D. Ramsay (1950) and N. Davidson and co-workers (1951). It is based on a rapid photolysis effected by an intense flash, followed by a second flash from a small lamp acting as a light source for absorption spectroscopy. Reactions can be studied at time intervals as short as 10^{-9} sec. after they are initiated, although most work based on this method has been carried out on microsecond and millisecond time scales. The method has been particularly successful for identification of spectra of small transient species like the radicals NH_2, HCO, NCO, CH_3, and CH_2 and of more complex species like the phenyl radical (C_6H_5). Gases, liquids, and solids can be examined by flash-kinetic spectroscopy to determine the time dependence of the absorption spectrum. One way this can be carried out is to do a series of photolyses, taking spectra at progressively later times after photolysis and accumulating the data experiment by experiment. An alternative procedure makes use either of a photographic film moving past a fixed image or a moving image of the spectrum traveling along a fixed film. Either gives a streak spectrum photograph, in which wavelength varies along one direction on the film in the conventional way and the time of incidence varies in the other direction. The streak spectrum is thus a continuous representation of the spectrum of the reacting system. Time-resolved spectra have been used to determine the lifetimes of triplet excited states, to measure the rates of product formation, and even to measure the quantitative dependence of rates on concentrations, in cases where spectral intensities can be measured quantitatively. The limitations of the method are twofold. First, the method requires that the transient species absorb in the spectral wavelength region being observed; and it must absorb strongly enough to be detected in the presence of unphotolyzed starting material.

Second, it is not always possible to identify the absorber from its spectrum alone; this is a much greater problem with large polyatomic molecules than with small molecules, but even there identification can cause considerable difficulty.

As a complement to optical absorption spectrum of a rapidly reacting mixture, one can study the time dependence of the mass spectrum. G. B. Kistiakowsky and P. H. Kydd (1957) introduced the time-of-flight mass spectrometer into photochemistry to study reactions of ketene ($CH_2{:}CO$) and of NO_2. This device is capable of scanning the mass spectrum of a gas being sampled as often as once every 10^{-5} sec. The appearance of a particular mass only during the middle stages of a reaction indicates that the mass is associated with an intermediate, which may be either a transient electronically-excited state of one of the starting materials or products, or a true intermediate species. It is generally possible to identify the mass of each intermediate and to distinguish it from its own fragments which are formed in the mass spectrometer (and not in the reaction). A combination of kinetic mass spectrometry with optical flash-kinetic spectroscopy can sometimes solve a photolytic kinetic problem almost completely, as in the case of the flash-photolytically generated transient species benzyne (C_6H_4); this species was identified and its rate of reaction ($2C_6H_4 \rightarrow C_{12}H_8$, biphenylene) was measured by just such a combination of techniques.

Flash methods use a sharp pulse of light to carry out the photoexcitation step. Two other approaches based on discontinuous illumination are also useful. In one approach, the exciting light is simply turned on (or off) very suddenly and left that way, while the concentration of intermediates, starting materials, and products changes. Any fast method of monitoring the concentrations (usually absorption spectroscopy) is used to follow the actual change. What is actually measured is a relaxation time for the concentration being observed; *i.e.*, the time it takes for the chemical system to adjust to the instantaneous change in the light level.

In the second approach, the light is made to vary periodically (most commonly just on-off, but it may vary sinusoidally). With this technique the rate of reaction is most easily found by varying the rate of alternation of light and dark, and measuring the dependence of stationary concentrations as a function of this frequency. If the switching frequency is faster than the chemical relaxation time the system will begin to respond as though the light was continuous at an intensity level corresponding to the average illumination from the intermittent lamp.

Possibly the most fundamental quantitative measurement of a photochemical process is that of quantum yield, or actinometry. This process may be carried out from a knowledge of the absolute emission characteristics of the exciting source and of the absolute absorbing ability of the absorbing species; or the measurement may be made as a relative one, by using as a comparison and standard a reaction whose absolute quantum yield is precisely known. Absolute measurements are usually much more difficult than relative ones, so the relative method is more common; but the standards must come from absolute measurements. Absolute measurements have been made of rates of the photo-ionization of atoms (*e.g.*, by H. Beutler, 1933–40; R. W. Ditchburn, 1928–60) and molecules (*e.g.*, by M. G. Inghram, 1960; J. D. Morrison, 1960; G. L. Weissler, 1952–58), and of the photodetachment of electrons from negative ions (by L. M. Branscomb and co-workers, 1958). In these undertakings the light intensity, emitted electron current, and, where appropriate, the atom concentration and ion current had to be measured absolutely. Other absolute measurements have been based on measurements of light intensity, absorption coefficient, and the number of moles of a characteristic product.

Light intensities can be measured with thermocouples, bolometers (*q.v.*), photomultipliers, or photoconductive devices. These detectors all give signals whose strength varies directly with the intensity of the light incident on them, but only the thermocouple and bolometer detectors are also relatively independent of the wavelength of the light. Detectors are ultimately calibrated in terms of standard sources whose spectral properties are well known. One of the common standards is a block of carbon floating

in gold, at the melting temperature of gold, 1,063° C. The radiation from such a source, which is a nearly perfect radiator, follows Planck's radiation law well enough that its absolute intensity at all wavelengths is rather precisely known.

The actinometer (*q.v.*) that is most reliable for solutions makes use of the photolytic decomposition of highly purified uranyl oxalate. It was developed by G. S. Forbes and his co-workers (1930–34). The net reaction is the decomposition of oxalic acid: $H_2C_2O_4 + h\nu \rightarrow H_2O + CO_2 + CO$. The amount of unreacted oxalate can be determined quite precisely by titrating the solution with permanganate. The quantum yield of this reaction is well established as a function of wavelength, temperature, intensity, and concentration of various ions, particularly hydrogen ions. For gas phase actinometry, other reactions are available; *e.g.*, the photolysis of hydrogen iodide, whose quantum yield is precisely 2 for a wide range of conditions.

Determining the Mechanisms.—Determining the actual path of a photochemical reaction frequently requires setting up hypothetical models corresponding to different possible mechanisms; finding from its kinetic equations how each model system depends on concentrations, light intensity, and any other pertinent variables; and then deciding, from experimental variation of these variables, which model best describes the system. (*See* REACTION KINETICS.) This is how a succession of investigators have shown how simple alkyl iodides, *e.g.*, CH_3I, decompose on photolysis and how the fragments must react. The methyl iodide system is interesting in that at least part of the energy of the absorbed photon stays in the reactive species long enough to assist in one crucial step. The steps of the mechanism and the variables used to determine the role of each step are as follows:

(1) Primary step:

$CH_3I + h\nu$ (near ultraviolet) → $CH_3 + I$	Quantum yield approximately 1, shown by independent use of scavengers for iodine and CH_3; presence of radicals shown by kinetic spectroscopy

(2) Normal secondary steps (M = inert collision partner to carry away energy):

$2CH_3 (+M) \rightarrow C_2H_6 (+M)$ $2I (+M) \rightarrow I_2 (+M)$	From product analysis

(3) Inhibiting secondary steps (recombinations):

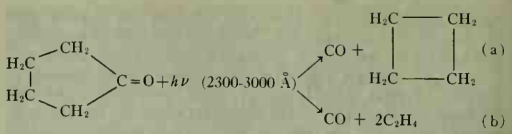
$CH_3 + I \rightarrow CH_3 + I$	Rate determined from low-pressure, low-intensity photolyses to minimize three-body reactions
$CH_3 + I + M \rightarrow CH_3I + M$	Rate determined from high-intensity photolysis to maximize frequency of radical-radical collisions

(4) Other secondary steps:

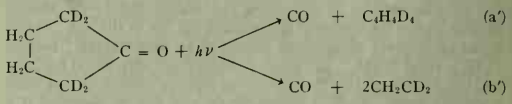
$CH_3 + CH_3I \rightarrow CH_4 + CH_2I$	Inferred from methane in products; thermochemistry requires either reactant to have 9 kcal/mole excess energy
$CH_2I + I (+M) \rightarrow CH_2I_2 (+M)$	From CH_2I_2 in products
$2CH_2I \rightarrow CH_2ICH_2I$	From 1, 2-di-iodoethane in products

The presence of activation energy in either CH_3 radical or the CH_3I molecule is confirmed by the quenching effect of foreign gases and the rise of quantum yield of methane (CH_4) as the photon energy is increased. The actual photon energy is about 50 kcal/mole or more, so that only a small fraction of this need remain available for the methane-formation reaction.

Other than direct detection of intermediates, the most powerful tool for elucidating mechanisms is probably the use of isotopic labeling. For example, deuterium can be used in place of hydrogen, or one of the other carbon isotopes instead of C^{12}, at selected sites in the starting material; the tagged atoms then can be located at particular positions in the product molecules. A method that is similar but not quite so clear-cut is the use of relatively inert substituents like alkyl groups on carbon atoms. An example of the unequivocal information isotopic substitution can give in a favourable case is in the photolytic decarboxylation (loss of carbon monoxide) of cyclopentanone. The process has alternative paths (a) and (b):



The use of a specific tetradeuterated species shows that the paths are mutually exclusive. No C_2D_4 is formed and therefore the ethylene cannot be a product of an intermediate in which all four carbon atoms are equivalent. The isotopically labeled reaction is this:



Another application of isotopic labeling occurs in photosensitized reactions. For example, a photoexcited mercury atom gives up its excitation directly to a collision partner, which may be an unexcited mercury atom or a complex molecule. If it collides with a complex molecule the mercury atom may simply transfer its energy or it may react to form a mercury compound which can be isolated as a product. Suppose the mercury photoexcitation is effected by a cool, low-pressure lamp containing a single pure mercury isotope. Since each isotope radiates a characteristic spectrum, and in a cooled low-pressure lamp the spectral lines are well separated, the light from a monoisotopic lamp will excite only those mercury atoms in the sample cell which are the same isotope as that in the lamp. If the product (the mercury compound formed in the photosensitized reaction) contains the same pure mercury isotope as the lamp, the observer knows that the product is formed in a single step involving excited mercury and the complex starting material. If, on the other hand, the mercury in the product has the normal mixed isotopic composition, the observer knows that the product was formed after the photoexcited mercury had lost its extra quantum and returned to the pool of unexcited mercury atoms. This method shows that the direct reaction (a) is about one-third as efficient as the two-step process (b);

$$Hg^* + HCl \longrightarrow HgCl + H \quad (a)$$
$$Hg^* + HCl \longrightarrow Hg + Cl + H \quad (b)$$

The same result holds for the alkyl halides.

A good method (and one of the oldest in photochemistry) for determining both kinetic constants and mechanisms is the study of fluorescence quenching. If a large molecule (*e.g.*, anthracene, pyrene, or acridine) is photoexcited and does not react, in general it will fluoresce. If a species is added which reacts rapidly with the photoexcited substance, fluorescence will no longer occur; *i.e.*, it will be quenched. In practice, the quantum yield for fluorescence (ϕ) or the ratio of quanta absorbed to quanta emitted in fluorescence (I_a/I_f) is used for systems representing several concentrations of the nonfluorescing reactant. If $1/\phi$ or I_a/I_f is plotted as a function of the quencher concentration, then a simple reaction of the following type must give a linear dependence of $1/\phi$ or I_a/I_f on quencher concentration:

$A + h\nu \longrightarrow A^*$		(1)
$A^* \longrightarrow A + h\nu$	Fluorescence	(2)
$A^* + A$ (or B) $\longrightarrow A + A$ (or B)	Deactivation	(3)
$A^* \longrightarrow D_1 + D_2$ or $A^* + B \longrightarrow C$	Reaction	(4)

The slope of the line, for I_a/I_f, is the ratio of the rate constants for reaction (4) to that for fluorescence, while the intercept on the axis corresponding to zero concentration is 1+ (the ratio of the rate constant for deactivation to that for fluorescence). If ϕ is used, the roles of the constants for fluorescence and for deactivation are interchanged. This method was developed by O. Stern and M. Volmer (1919) and refined by many later workers. It has made possible the determination of the strengths of acids in excited electron states (T. Förster, 1949); of rate constants for formation of complexes with excited states (A. Weller, 1960); of the rate of

dimer formation in anthracene (E. J. Bowen and co-workers, 1939); and of rates of long-range transfer of energy (T. Förster, 1960 and previously).

Fluorescence has been the key to understanding two kinds of fundamental processes in the photochemistry of liquids and solids. In the first of these, investigated by S. Boudin (1930), H. Kautsky (1935), and G. N. Lewis and co-workers (1941), an irradiated glassy or liquid solution of an organic dye or aromatic species (*e.g.*, anthracene or pyrene) emits both its normal rapid fluorescence and slow phosphorescence radiation and, in addition, a delayed fluorescence whose emission rate is comparable to that of phosphorescence but whose spectral distribution is that of fluorescence. The intensity of delayed fluorescence relative to that of phosphorescence decreases as temperature is lowered. In the case of dyestuffs it was shown (C. A. Parker and C. G. Hatchard, 1961) that thermal excitation alone, from the upper state of the phosphorescence (triplet) to the slightly more energetic fluorescing excited singlet state, led to the delayed fluorescence. The delayed fluorescence of anthracene and other aromatics, by contrast, exhibits a temperature dependence too complex to be due to the simple re-excitation mechanism; moreover its intensity depends on the square of the incident light intensity, so two quanta must be involved. The responsible mechanism is the collision of two long-lived triplets, producing one excited fluorescing singlet and one normal unexcited singlet.

The second photochemical process, which often appears in systems which also exhibit delayed fluorescence, is the formation of dimers in the excited state only. These photodimers of molecules or atoms that do not combine in their ground state are called excimers (B. Stevens, 1961); their existence was first proven in irradiated solutions of pyrene (T. Förster and K. Kasper, 1955). Excimers can fluoresce normally or in a delayed process. They play an important role in the mechanism of the action of plastic (polystyrene) scintillation counters (F. Hirayama, 1963). An excited phenyl ring interacts with a neighbouring ground-state ring along the chain to form an excimer—provided the chain is flexible enough for the rings to come close together (M. Vala and S. A. Rice, 1964). Photoexcited atoms (*e.g.*, of argon, krypton, and xenon) form excimers in solid, liquid, and gas phases. In both atoms and molecules, chemical binding of excimers occurs in the excited state only because in that state one antibonding electron is removed from the immediate vicinity of the two atoms, permitting the effect of the bonding electrons to dominate over the remaining antibonding electrons.

APPLICATIONS

Synthetic Chemistry.—Since absorption of a light quantum is frequently a property of a single group within a molecule, photochemistry sometimes offers a highly specified tool for including a chemical reaction at a specific molecular site. This becomes especially valuable in cases where thermal excitation would be very unspecific or where heat would destroy the reactant. Photochemical syntheses include the formation of valence tautomers, isomers, and single dimers, and elimination reactions.

Photolytic syntheses are sometimes most effective if the reactants are held rigidly by a solid lattice so that a reactant molecule absorbing a quantum is in a favourable and fixed orientation for reaction. Solid-state photolyses of this kind have been used by G. Griffin and co-workers in the synthesis of the dimers of maleic and fumaric acids (1960). The photographic process is essentially a photoinitiated synthetic process in a solid. The property peculiar to solids which the photographic process uses is the easy diffusion of both the photoexcited electron and the vacancy it leaves on a halide ion. Eventually the electron vacancy can diffuse to a crystal surface to form neutral bromine, forcing the electron to recombine with a positive silver ion and thus giving a neutral atom.

Radiation Chemistry.—The photochemistry associated with high-energy radiation (X rays and gamma rays) is closer to the chemistry of electron-bombarded materials than to the photochemistry of visible-ultraviolet radiation. This is because a high-energy process (radiolysis) of electron or photon bombardment produces ionized species in addition to excited neutrals, and these ionized species are products of very fast secondary processes, not of the primary quantum absorption process. The primary processes associated with high-energy radiation are simply too fast to lead to any chemistry in the traditional sense of bond formation or breakage. Radiation chemistry is largely concerned with determining what the first-formed new chemical species are and what reactions they undergo. Three examples of radiolysis will exhibit the extent of this branch of photochemistry:

1. Since the chemical species differ from their precursors by one or more charges, it is natural to examine oxidation-reduction ("redox") processes induced by gamma-radiolysis. One type of radiolytic redox reaction involves a rigid organic glass containing a substance (*e.g.*, paraphenylenediamine) which is susceptible to oxidation processes. Radiolysis leads first to mobile electron vacancies or electronic excitation in the solvent; this travels rapidly through the glass until it meets a solute molecule, and then oxidizes the paraphenylenediamine, leaving an ion or ion-pair (W. H. Hamill and co-workers, 1964).

2. Radiolysis is a natural approach in the study of ion-molecule reactions and, in the gas phase, ion-radical reactions and the secondary processes leading to the final ions. Ions are very reactive toward neutral molecules because their attractive force of interaction is rather long-range, varying as the inverse fifth power (r^{-5}) of their separation, instead of the inverse seventh power. A saturated-hydrocarbon ion-molecule colliding with neutrals readily undergoes transfer of an atom of hydrogen, a proton, or a negative hydride ion with a frequency comparable to the collision frequency of the neutral parent molecules with each other. In liquids, large free radicals and ion-molecules are produced, but in solids it seems that the cage effect of the lattice prohibits formation and diffusion of radicals. In condensed phases the ion-molecules react with their neighbours or intramolecularly to form H_2 and either unsaturated monomers or dimers (L. Kevan and W. F. Libby, 1962). In the gas phase, ion-molecules often break into fragments when ionization occurs, both because of the large energy delivered directly by the ionizing radiation and, more specifically, because the ion-molecule, formed almost instantaneously so far as the atomic nuclei are concerned (*i.e.*, according to the Franck-Condon principle), is produced in a state of very high internal potential energy—higher than that of dissociated fragments. The newly produced ion-molecule dissociates unless its excess energy is removed by collisions before the fragments can escape from each other. In a gas these collisions are not available; in a liquid or solid they are (F. H. Field, J. L. Franklin and co-workers, 1957–64).

3. The action of high-energy radiation on water and water solutions is a fundamental problem of radiolysis. Radiolysis of aqueous solutions characteristically produces reducing species; *i.e.*, molecular species which eventually add electrons to solute species capable of accepting them; *e.g.*, the ferricyanide ion $Fe(CN)_6^{3-}$, which can be converted to the ferrocyanide ion $Fe(CN)_6^{4-}$ by addition of an electron. The water radiolysis problem depends directly on determining the reducing species and characterizing them. In strong acid, at least one reducing species is the hydrogen atom; in neutral and basic solutions, both OH radicals and hydrated (or solvated) electrons are formed by the radiation. The solvated electron was first characterized by its kinetic properties and then by its absorption spectrum (M. S. Matheson and co-workers, J. W. Boag, 1963); the OH radical was long a well-known species from a wide variety of spectral and chemical properties.

Radiation chemistry assumes a particularly important role in the understanding of how living beings react to radiation and how they can be protected against its damaging effects. (*See* RADIATION: BIOLOGICAL EFFECTS.) Chemical protection can be accomplished to some degree with an amino acid cysteine and other compounds containing sulfur-hydrogen bonds. Elucidating the role of these compounds as traps for free radicals, as hydrogen sources or as fast scavengers for OH or hydrated electrons, is a major task of radiation chemistry.

Studies of the Atmosphere.—The phenomena of terrestrial

and planetary atmospheres, *e.g.*, atmospheric structure, auroras, radiation shielding, and weather, depend on the chemical constituents of the atmosphere and the radiation striking it. The earth's atmosphere is largely molecular nitrogen and molecular oxygen at the earth's surface but contains quite a different set of atomic and molecular components at high altitudes, largely because of the radiation that these upper layers absorb. The upper ionospheric, or F, layers, at heights of 150 to 300 km. (100 to 200 mi.), contain high proportions of electrons and ions; there the ion concentration is about 10^6 per cubic cm. in a total density of 10^9 particles per cubic cm.—enough to reflect relatively long radio waves effectively. The ionic constituents or the F layers are largely O^+, O_2^+, O_3^+, N^+, and N_2^+.

The most important photochemical reactions occur in the lower part of the F layers and the upper part of the lower ionospheric, or E, layers. There, oxygen molecules are photodissociated into atoms by sunlight. The oxygen atoms react with O_2 molecules to form ozone. The ozone then absorbs virtually all the solar radiation between 3000 Å and 2200 Å, protecting the earth's surface from what would be very intense energetic radiation, quite harmful to life as it now exists. The ozone is converted into $O_2 + O$ by this absorption, and the oxygen atoms can also be excited; *e.g.*, to a state whose radiation is responsible for the green auroral line (5577 Å). The most important mechanism for this process is probably $3O \longrightarrow O_2 + O^*$. Other kinds of excitation by radiation are also important in the atmosphere. The excited N_2^+ ions responsible for the blue color in the aurora are produced indirectly by high-energy ionizing particles from space. The secondary electrons produced by the high-energy particles collide with nitrogen molecules and simultaneously excite and ionize them.

Photochemical processes control another atmospheric process: air pollution and smog formation. There are several types of smog; typically they are dispersions of very small droplets or particles of reaction products suspended in air, and often contain irritating and corrosive materials. The origins of smog are varied, depending on substances distributed into the atmosphere. An automobile exhaust smog like that of Los Angeles, Calif., occurs when a mixture of unsaturated hydrocarbons (*e.g.*, ethylene), nitrogen oxides (NO and NO_2), and frequently sulfur dioxide is irradiated in air. The NO_2 and perhaps the SO_2 absorb light and react with hydrocarbons, ultimately photooxidizing the hydrocarbons to formaldehyde, acrolein, PAN (probably peroxyacetylnitrate, $CH_3(CO)OONO_2$, but unproven because of its explosive character), and other less irritating materials. The detailed mechanisms and even many of the reactions are not known; however, it is known that oxygen atoms and ozone are present, that NO_2 is regenerated by chain mechanisms probably involving higher oxides of nitrogen, and that sulfur dioxide greatly enhances the formation of suspended droplets in the photooxidation process.

Biological Processes.—The most important photochemical processes of living systems have already been mentioned. They include photosynthesis (*q.v.*), or the reduction of CO_2 to carbohydrates by the action of light on photosynthetic pigments such as chlorophyll; vision, or the absorption of light quanta by retinal pigments; photoinduced activation of vitamin D by way of a photochemical rearrangement; the damaging action of high-energy radiation, which involves inactivation of sulfur-containing enzymes, at least in part. (But even irradiated water can be toxic to living species.) On the periphery of photochemical phenomena in biology is bioluminescence (*q.v.*).

Photosynthesis, apart from its role in plant metabolism, is a unique and exceedingly complex photochemical process. It involves the absorption of eight quanta of radiation for every CO_2 molecule used, and these eight quanta are divided equally between two different pigment systems. Both systems contain at least one pure pigment in common, chlorophyll *a;* at least one system also contains accessory pigments. Moreover, light seems to be required by a plant for the manufacture of chlorophyll itself. When one also considers the elaborate chain of secondary oxidation-reduction-energy transfer steps, it is clear that the photosynthetic mechanism is much more intricate than any of the one-quantum or two-quanta processes discussed previously—so much so that these processes are almost qualitatively different from photosynthesis.

Photophysical Phenomena.—"Photophysical" is a convenient label for phenomena intimately related to those investigated in photochemistry but not part of the mainstream of photochemical kinetics. They involve some change in a physical property due to the action of light; therefore they may be classified among phenomena representing the transition from chemical to physical processes. Photochromism, photoconductivity, and some aspects of laser action are among these processes.

Photochromism.—One such phenomenon is photochromism, the reversible production of colour or of a change in colour of a substance by the action of light. Most organic photochromic materials actually undergo rearrangements, photooxidations, or photoreductions when they exhibit their peculiarity. In this sense their photoprocesses are no different from those discussed previously, except that the photoproducts of photochromes happen to absorb visible light. Some materials do not make use of rearrangements or other reactions in their photochromic mechanism. These require that a coloured "photo-accessible" state of some constituent be relatively stable. Triplet states sometimes satisfy this criterion; *e.g.*, photoexcited triphenylene in a hydrocarbon glass remains as a stable coloured triplet with a 20-min. half-life. Impurity centres in inorganic crystals (*e.g.*, traces of manganese or bismuth in calcium sulfide) are photochromic, usually as a result of photooxidation of the impurity ion. Another type of photochromism is the formation of colour centres in alkali halide crystals; *e.g.*, NaCl. (These centres are known as F centres, from Ger. *Farbe*, "colour.") Photoexcitation removes an electron from a halide ion, just as it does in a silver halide in photography. The electron then becomes trapped in a lattice vacancy to form a F centre; its colour appears because the energy required to free the trapped electron corresponds to a quantum of visible light.

Photoconductivity.—If light is absorbed by a solid, the electrons excited by the absorption process may have enough energy to leave the solid altogether. This is the photoelectric effect discussed previously. When insulating materials are irradiated, often the electrons do not have sufficient energy to escape from the material but are able to move more or less freely through the solid. Whenever the excited electrons do remain mobile but bound to the bulk material, they are able to drift, and more particularly to move under the influence of an electric field, and therefore to act as carriers for electric current. Without photoexcitation the electrons are essentially immobile: in an insulator, in general, the unexcited electrons cannot move from a quantum state located on one atom to a state on the next atom because all the available states are already filled. If an electron has been removed from one atom, *e.g.*, by photoexcitation, then it leaves a vacancy in the quantum shell where it originated. Such a vacancy, or "hole," is available for an electron on a neighbouring atom, allowing that electron to move, and therefore for the hole to move. This kind of motion can continue, so that the hole drifts through the insulator, behaving very much like an electron except that it moves in the opposite direction.

Electrons and holes both share in carrying the electric current in the phenomenon of photoconductivity. If unexcited electrons can move easily from site to site whenever a hole is available, then the mobility of the hole is high and it is an efficient current-carrier. Similarly, if the excited electron can move easily without losing its energy or being diverted by collisions, it will have a high mobility and carry current easily.

Among examples of photoconductors are those first observed by R. W. Pohl and his co-workers (1924–38). These included diamond, zinc-blende, the alkali halides, and the silver halides. Pure germanium is a photoconductor when it absorbs infrared radiation of energy greater than about 0.6–0.7 ev. Naphthalene and anthracene photoconduct when they absorb ultraviolet radiation; cadmium sulfide will do so under the action of the 4580Å line of mercury. Even liquid solutions of hydrocarbons will photoconduct when they are sufficiently concentrated.

Laser Action.—Another photophysical phenomenon is that associated with light amplification, or laser action. ("Laser" is an

acronym for "light amplification by stimulated emission of radiation.") A molecular system containing stored energy may radiate this energy spontaneously in a spectral line at frequency ν, or it can be stimulated to emit the energy by applying weak radiation of frequency ν to the system. Molecular amplification of radiation was first observed by J. P. Gordon, H. J. Zeiger, and C. H. Townes (1955) for a characteristic microwave frequency of ammonia. T. H. Maiman (1960) demonstrated that the same process occurs with visible light, the 6940 Å line of chromium in ruby. Since then, many systems—gaseous, liquid, and solid—have been found which act as lasers. To produce laser action, energy is "pumped" into the storage atoms or molecules with a high-intensity flash lamp; the exciting light contains a rather broad spectrum of frequencies. Then, in a properly designed and tuned system, the slightest stimulus will cause most of the stored energy to be radiated in a single narrow spectral line. From a photochemical standpoint, the process depends on the existence of a set of energy levels which make it possible for a system to absorb large amounts of light and then release it in a single line without reabsorbing it. The resulting beam of light can be made virtually nondivergent, so that it can be propagated for astronomical distances; it can be produced with extremely high intensity, so that it can produce harmonics or overtones of its own frequency when it passes through an appropriate material; or it can be focused to a point where the field is intense enough to explode air or to be a surgical tool for exceedingly delicate operations. (R. S. Be.)

PHOTOELECTRICITY (literally, "light electricity") is the study of certain changes of an electrical nature induced in matter by light and other forms of radiation. When the primary result of the absorption of electromagnetic radiation by matter is the dissociation of the matter into electrically charged particles, the process is designated a photoelectric effect. As commonly investigated, with radiation lying between the X-ray and infrared limits of the electromagnetic spectrum, the photoelectric effect results in the ejection of electrons from the atoms of which matter is composed. The γ rays whose energy exceeds 1 Mev (million electron volts) may create pairs of positive and negative electrons. The γ rays whose energy is very large ($\sim$ 300 Mev) may create π mesons (*see* Particles, Elementary).

The study of the photoelectric effect was of major importance for the development of physical theory during the first two decades of the 20th century. The role played by the photoelectric effect during this period was largely due to the unambiguous manner in which it displayed the quantum properties of radiation which are not describable by the electromagnetic wave theory of James Clerk Maxwell. (*See* Electricity; Electromagnetic Waves.)

In addition, observation of the behaviour of photoelectrons was of the greatest aid in solving the riddle of atomic structure. For these reasons a brief survey will be given of the early history of the photoelectric effect, after which the photoelectric effect of high-frequency radiation and of low-frequency radiation, applications of the photoelectric effect, and nuclear photoeffects are discussed. This article, therefore, is divided into the following sections:

I. Historical Survey
II. Photoelectric Effect of High-Frequency Radiation
  1. Direction of Emission
  2. Compton Effect
  3. Auger Effect
III. Photoelectric Effect of Low-Frequency Radiation
  1. Metals
  2. Insulators
  3. Gases
  4. Photovoltaic Effects
IV. Applications of the Photoelectric Effect
V. Nuclear Photoeffects

I. HISTORICAL SURVEY

E. Becquerel, in 1839, reported that the illumination of one of a pair of metal plates immersed in a dilute acid solution altered the electromotive force of the cell. The decrease in the electrical resistance of selenium on illumination was discovered by Willoughby Smith in 1873. These photoelectric phenomena attracted great interest at the time of their announcement but remained unexplained and isolated observations.

In 1887 Heinrich Hertz observed that the behaviour of a spark gap was affected by illumination of the electrodes. W. Hallwachs investigated Hertz's observation and in the following year reported that a clean, insulated zinc plate acquired a positive charge on illumination with ultraviolet light. A negatively charged plate could be made to lose its charge by illumination. The effect was found to persist if the metal was placed in a vacuum.

In 1900, three years after the discovery of the fundamental particle of negative electricity, the electron, Philipp Lenard proved that the effects observed by Hallwachs were due to the ejection of electrons from the metal under the stimulus of radiation. It was found that the effect was a common property of metals but that only a few (*i.e.*, the alkali metals and some alkaline earth metals) were sensitive to visible light. In general, it was necessary to use ultraviolet radiation to provoke the effect.

J. Elster and H. Geitel discovered in 1900 that the number of photoelectrons emitted per second from the surface of a metal is proportional to the intensity of the incident radiation. Lenard established in 1902 the important fact that the maximum kinetic energy of a photoelectron depends only on the frequency of the incident radiation and is independent of its intensity.

According to Maxwell's theory, radiation consists of an electric and a magnetic field propagated through space in the form of a transverse wave. The constant velocity c of propagation in a vacuum is the product of the wavelength of the wave and the frequency of vibration of the electric and magnetic vectors. The energy transferred by the wave across unit area perpendicular to the direction of propagation in unit time is the intensity of the radiation and is proportional to the square of the amplitude of the electric vector.

It was believed that the electric field of the radiation exerted a force upon the electron which freed it from the atom to which it was bound. It was difficult to understand from the theory of Maxwell how the kinetic energy of the electron can be independent of the intensity of the radiation, which is fixed by the magnitude of the electric field.

This difficulty was ascribed by A. Einstein to a fundamental incompleteness of the Maxwellian wave theory of radiant energy. Einstein proposed that radiation possessed many of the properties commonly associated with material particles. In particular, he suggested that in a beam of radiation of frequency ν, the energy exists in the form of units of magnitude $h\nu$. The names photon and quantum are given interchangeably to these units of radiant energy. Einstein viewed the photoelectric process as one in which an electron absorbs a photon. The kinetic energy of the free photoelectron is the difference between the energy it has absorbed and the work it has performed in its escape from the forces binding it to the atom. Einstein proposed in 1905 the simple relation

$$T = h\nu - w \qquad (1)$$

between the maximum kinetic energy, T, of the free photoelectron and the frequency, ν, of the radiation. The constant w is the mini-

mum work which the electron must perform to escape from the material to which it is bound. Einstein predicted that the constant h would be found to be the same constant which Max Planck had previously introduced into theoretical physics in discussing the emission of radiation from matter.

The experimental data available in 1905 did no more than suggest the correctness of these conclusions, but by 1916 the validity of Einstein's relation between the maximum kinetic energy of a photoelectron and the frequency of the absorbed radiation had been fully confirmed. This was largely the result of the beautiful experimental work of Robert Millikan, whose measurements also determined Planck's constant, h, with great precision.

Photoelectric phenomena present another major difficulty to Maxwell's theory of radiation. It was estimated by Lord Rayleigh in 1916 that according to Maxwell's theory it would take a time of the order of several hours for an electron to absorb sufficient energy from a beam of radiation to escape from an atom. But Elster and Geitel had noted that the appearance of photoelectrons occurred simultaneously with the illumination of a metal surface. In fact, E. O. Lawrence and J. W. Beams, in 1928, found that the time lag between the incidence of radiation and the appearance of photoelectrons was less than 3×10^{-9} seconds. The experiments of A. T. Forrester and his co-workers established in 1955 that the interval between illumination and photoemission is less than 10^{-10} sec. If the photoelectric effect is initiated by the collision of two corpuscles, the electron and the photon, then there is no difficulty in understanding the instantaneous character of the emission.

The success of the photon hypothesis in yielding the Einstein equation (1) and in interpreting other photoelectric phenomena stands in sharp contrast to the successful application of the wave theory of radiation to the field of interference and diffraction effects. (*See* LIGHT.) It appears that a dual character must be ascribed to radiation and that a complete description of its interaction with matter cannot be obtained by the consistent use of either a wave or a corpuscular theory. (*See* QUANTUM MECHANICS.)

II. PHOTOELECTRIC EFFECT OF HIGH-FREQUENCY RADIATION

Radiations whose wave lengths lie between 100 and 0.01 angstroms are termed X-rays. The angstrom unit of length, named in honour of the Swedish spectroscopist A. Ångström, is equal to a hundred millionth of a centimetre (1×10^{-10} m.). X-rays are commonly produced by the impact of fast electrons upon matter (*see* X-RAYS); γ rays are of even shorter wave length and are emitted by the nuclei of radioactive atoms.

The photoelectric effect of high-frequency radiation in gases is easily demonstrated with an instrument known as an ionization chamber. This consists of a closed box filled with the gas. A thin window of metal foil or mica allows entrance of the X-ray beam. Inside the chamber are a pair of metal electrodes. By connecting the electrodes to the terminals of a battery an electric field is established between them. A gas under normal conditions is a good electrical insulator and no current will pass between the electrodes.

When X-rays enter the chamber, the photoelectrons and the positive ions formed from the atoms which have lost electrons are swept by the electric field to the electrodes and an electric current may be readily detected. The fast photoelectrons collide with the atoms of the gas and dislodge electrons from them so that the total number of electrons and positive ions is many times the number produced photoelectrically.

The photoelectrons produced by X and γ radiation possess very large kinetic energies and, therefore, very high velocities. The velocities commonly approach the speed of light and necessitate the use of relativistic equations in the discussion of their motion. The kinetic energies correspond to those acquired by electrons which have been accelerated by potentials of many thousands of volts.

With an instrument known as a β-ray spectrograph, H. Robinson and his co-workers performed some very informative experiments. This device, the use of which was introduced by O. Hahn, L. Meitner and C. D. Ellis, is illustrated in fig. 1. Robinson allowed X-rays of known frequency to impinge upon a solid placed in the position indicated. A fraction of the photoelectrons emitted by the solid pass through the slit and enter the evacuated chamber.

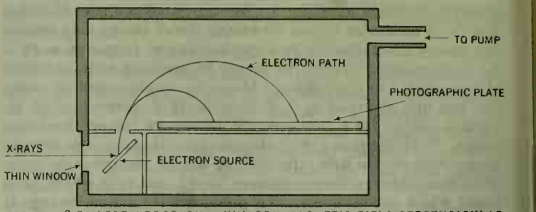

FIG. 1.—β-RAY SPECTROGRAPH. UNIFORM MAGNETIC FIELD PERPENDICULAR TO PLANE OF PAPER

Here they are bent in arcs of circles by a uniform magnetic field of known magnitude. The photoelectrons then fall upon the photographic plate leaving developable traces. The position of the traces and the dimensions of the apparatus determine the radii of the circular arcs traversed by the electrons. A knowledge of these radii and of the magnitude of the magnetic field makes calculable the velocities of the electrons.

Robinson tested Einstein's equation with X-rays of known frequency. The energy lost by a photoelectron in escaping from an atom of a given chemical element (the quantity w) was found to assume several sharply defined values. This behaviour was direct evidence for the existence of atomic energy levels.

If radiation of unknown frequency is allowed to eject electrons from an element whose atomic energy levels have been determined, the unknown frequency may be determined by the use of Einstein's equation after measurement of the kinetic energies of the photoelectrons with the β-ray spectrograph. In this manner, Ellis and M. de Broglie examined the γ rays emitted by many radioactive elements and established the very important fact that γ-ray spectra are discontinuous as are the atomic spectra of the elements. This important work was the beginning of a spectroscopy of the nucleus and the establishment of nuclear energy levels.

1. Direction of Emission.—An important problem connected with the photoelectric effect is the direction of emission of the electron by the radiation. According to Maxwell's theory, radiation consists of a transverse wave, and the direction of emission should be the direction of the force exerted upon the electron by the electric vector which lies in a plane perpendicular to the direction of propagation of the radiation. This problem may be investigated by using the photoelectric effect of X-rays upon a gas in a Wilson cloud chamber. (*See* CLOUD CHAMBERS.)

The Wilson chamber is a vessel in which a gas may be supersaturated with water vapour by a sudden expansion. A fast electron ejected from an atom by the radiation strikes other atoms in its passage through the gas. In this manner it ejects electrons from the atoms of the gas leaving the atoms positively charged. Water droplets condense upon the ions thus formed and render visible the path of the high-energy photoelectron.

If X-rays of long wave length (*i.e.*, low frequency) are used to produce the photoelectrons it is found that the most probable direction of emission is in the plane perpendicular to the direction of propagation of the X-rays. As the frequency of the X-rays is increased, the majority of the photoelectrons are emitted in a direction which makes an angle less than 90° with the direction of propagation of the wave. This effect is explained by the fact that in the photoelectric process the electron receives not only the energy, $h\nu$, but also the momentum, $h\nu/c$, of the photon. It is only when the frequency of the radiation is greater than that of soft X-rays that the momentum of the quantum is large enough to have a discernible effect upon the direction of emission of the electron.

Neither Maxwell's theory nor the simple photon hypothesis of Einstein is entirely successful in its description of the experi-

mental results. Maxwell's theory demands that all the electrons be ejected in the plane perpendicular to the direction of propagation of the radiation. The photon hypothesis predicts a definite angle between the perpendicular plane and the direction of emission which is approximately half that observed between the most probable direction of emission and the perpendicular plane. The quantum-mechanical treatment of the problem has met with considerable success. The observed variation in the direction of emission is correctly described and the effect of the quantum momentum upon the direction of emission is greater than predicted by the photon hypothesis.

2. Compton Effect.—A most unusual type of photoelectric effect is that in which in the act of absorption of the photon its full energy is not given to the photoelectron but a fraction is scattered as a quantum of smaller energy. (*See* COMPTON EFFECT.)

This phenomenon was originally observed in experiments upon the scattering of monochromatic X-rays by solids. Among the scattered X-rays there is radiation of the same wave length as that of the primary X-rays and two types of modified X-rays of longer wave length. Atoms which have absorbed quanta may reradiate energy as fluorescent radiation.

This fluorescent radiation contains wave lengths which are characteristic of the absorbing atoms and independent of the wave length of the primary X-rays and of the angle of observation. There is also present a scattered radiation whose wave length is dependent upon the wave length of the incident radiation and upon the angle which the direction of observation makes with the direction of the primary radiation.

The existence of this last-mentioned type of scattered radiation was established and a simple explanation of its origin was given by A. H. Compton in 1923. Compton suggested that, if radiation has the corpuscular character ascribed to it by Einstein, a quantum of energy $h\nu$ and momentum $h\nu/c$ might be conceived as making an elastic collision with a free electron whose kinetic energy before the collision is negligible by comparison with that of the quantum. The laws of conservation of energy and momentum, when applied to the collision, give at once a relation between the energy of the scattered quantum and the angle at which it is scattered. Expressed in terms of the difference in wave length between the scattered and incident quanta the relation is

$$\Delta\lambda = \left(\frac{h}{mc}\right)(1 - \cos\theta), \qquad (2)$$

where $\Delta\lambda$ is the difference in wave length, and θ is the angle of scattering. The constants h, m and c which enter the equation are Planck's constant, the electron mass and the velocity of light, respectively.

This equation agrees very closely with the results of experiment. Observation with Wilson cloud chambers has made possible the detection of the recoil electrons. The simultaneous appearance of the scattered quantum and the recoil electron at the predicted angles has been observed by experiments in gases with Geiger counters.

3. Auger Effect.—It was observed by C. T. R. Wilson in 1923 that the absorption of an X-ray quantum by an atom is accompanied occasionally by the emission of two or more electrons. In such a case, only one of the electrons has a kinetic energy which depends upon the frequency of the quantum in the manner described by Einstein's equation. The kinetic energy of the other electrons is characteristic of the type of atom. These facts were established by P. Auger in an extensive investigation of the phenomenon.

The explanation of the Auger effect is as follows. A tightly bound electron is first ejected from the atom by the usual photoelectric process. Such an electron is one for which the constant w in Einstein's equation is large. After the act of photoelectric emission the atom is left with the excess energy, w. The atom can decrease its energy by transferring an electron from a higher energy level to the one vacated by the photoelectron. In the course of this transition the atom loses energy, usually by the emission of a quantum of radiation. Occasionally the energy freed by the transition is given to one of the electrons of the atom which is ejected.

Such an Auger electron will appear outside the atom with a kinetic energy which is the difference between that given to it by the atom and the energy lost in escaping from the atom. Since each of these energies is determined by the atom, the kinetic energy of the Auger electron is characteristic of the atomic species.

In stripping itself of its excess energy the atom may emit more than one quantum and several Auger electrons. The total energy so lost cannot be greater than w, the excess energy with which the atom was left as a result of the initial photoelectric act.

III. PHOTOELECTRIC EFFECT OF LOW-FREQUENCY RADIATION

The wave-length region from 2,000 to 10,000 angstroms (Å) is of primary importance for photoelectric studies. The opacity of air and most optical materials has severely limited work in the region below 2,000 Å. The quanta of infrared radiation of wave lengths longer than 10,000 Å possess so little energy that they produce photoelectric effects in few substances. Visible radiation, or light, includes the wave-length region from about 4,000 to 7,000 Å.

1. Metals.—The most important topic of investigation with low-frequency radiation has been emission from the surfaces of metals. In this case, the constant w of Einstein's equation is known as the work function of the metallic surface. A brief discussion of the structure of a metal is necessary in order to understand the significance of the work function.

The large electrical conductivity of metals is attributed to the presence of electrons which are not bound to particular atoms but are free to roam the interior of the metal. At the surface the electrons are subject to forces which prevent them from leaving the metal. The number of free electrons is of the same order of magnitude as the number of atoms. The minimum work which must be performed against the surface forces to extract an electron from the metal is the work function.

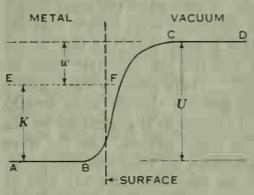

FIG. 2.—ENERGY DIAGRAM FOR AN ELECTRON AT THE SURFACE OF A METAL

This discussion may be amplified by reference to fig. 2. The heavy solid line, ABCD, represents the potential energy of an electron in the neighbourhood of the surface. It is assumed that inside the metal the potential is constant as indicated by the horizontal part, AB, of the line. In passing through the surface the potential energy increases suddenly as shown by the portion, BC, of the line.

Outside the metal the potential energy is again constant along the line CD. To extract an electron, initially at rest inside the metal, would demand the work U. The electrons in the metal, however, have kinetic as well as potential energy. The kinetic energies vary between zero and a maximum value as indicated by the horizontal line, EF. The maximum kinetic energy of an electron inside the metal is K. The work necessary to extract the fastest electron and leave it with zero kinetic energy outside the metal is the difference between U and K (or w), the work function. The equation

$$h\nu = w \qquad (3)$$

determines the photoelectric threshold frequency. Radiation of smaller frequency is incapable of ejecting electrons. Equation (3) is the Einstein equation (1) with the kinetic energy T of the photoelectron set equal to zero. For most metals the photoelectric threshold is in the ultraviolet. Tungsten has a work function of 4.53 electron volts (ev) which corresponds to a threshold wave length of 2,730 Å. This is well into the ultraviolet. Sodium has a work function of 2.28 ev or a threshold wave length of 5,400 Å, which is in the green of the visible spectrum. The electron volt is a common unit of work or energy in photoelectric studies and is the work necessary to move an electron through a potential difference of one volt.

FIG. 3.—PHOTOELECTRIC YIELD OF BARIUM AS A FUNCTION OF WAVE LENGTH EXPRESSED IN AMPERES PER WATT OF INCIDENT RADIATION. THE EFFECT OF REFLECTION IS INCLUDED IN THE THEORETICAL CURVE

It has been found that the work function is extremely sensitive to the presence of traces of impurities upon the surface of the metal. If the characteristic work function of a metal is to be measured it is necessary to remove all traces of absorbed gas from the surface, preferably by prolonged heating at as high a temperature as possible in a very good vacuum.

If monochromatic radiation is incident upon the surface of a metal, the photoelectric yield (*i.e.*, the number of electrons emitted for each quantum absorbed) is zero when the wave length of the radiation is longer than the threshold wave length. As the wave length of the incident radiation is made less than the threshold wave length, emission begins and the photoelectric yield increases with decreasing wave length. There exists a wave length for which the yield is a maximum and for shorter wave lengths than this the yield decreases. This behaviour is illustrated by the experimental curve of fig. 3 for the metal barium. As the wave length of the incident radiation decreases, its quantum energy increases and a greater fraction of the photoelectrons are able to escape from the metal. The existence of a maximum in the yield curve is not so immediately understandable. It results from the fact that the probability of absorption of a quantum by an electron decreases rapidly with increase of the frequency or decrease of wave length. This is a general feature of photoelectric absorption by electrons under all conditions.

The maximum in the photoelectric yield curve is then the result of a superposition of two effects. The shorter the wave length of the radiation the greater is the fraction of the electrons which will escape from the metal after the act of absorption. But the shorter the wave length, the smaller is the probability that any individual electron will absorb a quantum. For wave lengths less than that which corresponds to the maximum in the yield curve, the second effect is more important than the first.

Radiation incident upon the surface of a metal and not reflected is absorbed in a thin layer approximately a hundred thousandth of a centimetre in depth. The photoelectrons must come from this layer. I. Tamm and S. Schubin suggested that the majority of the photoelectrons are produced in a much thinner layer at the immediate surface of the metal. If the potential energy of an electron inside a metal is constant as drawn in fig. 2, it is easily demonstrated that only at the surface can photoelectric absorption occur. In the act of absorption the electron increases its energy by the amount $h\nu$ but its momentum increases by the negligible amount $h\nu/c$.

As a result, a free electron, which is one moving in a region of constant potential, cannot satisfy simultaneously the laws of conservation of energy and momentum during the act of photoelectric absorption of a quantum. The surface of the metal where the potential is rapidly changing may act as a third body and enable the conservation laws to be obeyed.

In actuality, the potential energy of an electron inside a metal is not constant and the possibility of photoelectric absorption by the electrons in the interior exists. Only photoelectrons produced in a thin layer approximately a ten millionth of a centimetre thick will have an appreciable probability of escape, however, since this is the order of magnitude of the distance traveled by an excited electron before making a collision with another electron in which it loses a substantial fraction of its energy.

Tamm and Schubin pointed out, however, that the threshold wave length for the emission of photoelectrons produced in the interior will be shorter than the threshold of the surface photoelectrons. Electrons at the surface can absorb quanta of any frequency and the work function of the metal determines the threshold. Selection rules, determined by momentum considerations, set a lower limit to the frequency of the quanta which may be absorbed by interior electrons. This lower limit of frequency varies from metal to metal but is always greater than the threshold frequency set by the work function for the surface photoelectric effect.

The theoretical curve of fig. 3 for barium was calculated according to the quantum-mechanical theory of K. Mitchell, who assumed that photoelectrons are produced only at the surface of the metal. It is not known to what extent the neglect of photoelectrons from the interior of the metal affects the divergence between the calculated and experimental curves. It is probable that the discrepancies are primarily due to an inadequate treatment of the behaviour of the radiation near the surface of the metal, where it is reflected and refracted.

The work function depends slightly upon the temperature of the metal. The most important reason for this effect is the variation of the kinetic energies of the electrons in the metal with temperature. At the absolute zero of temperature there is a definite upper limit to the kinetic energy of an electron as indicated in fig. 2.

At any finite temperature, the upper limit is not sharply defined but the probability that any electron possesses more than a definite amount of kinetic energy is small. An effect of this indefiniteness in the upper limit of the kinetic energy is that the photoelectric threshold is not well defined. R. Fowler and L. A. DuBridge developed approximate theories of the photoelectric effect which permit the determination of the work function that the metal would possess if the electrons were at the absolute zero of temperature. It is this fictitious work function which is usually tabulated and discussed.

If a metal is heated to a high temperature, an observable number of electrons obtain sufficient kinetic energy to escape. This is known as the thermionic effect. From the variation in the number of thermionic electrons with the temperature it is possible to determine the work function w. It is highly gratifying that work functions measured in this manner agree with the photoelectric work functions. This is especially true in so far as it affords a confirmation of the theory of Tamm and Schubin that, at least near the threshold, the photoelectrons are produced at the immediate surface of the metal (*see* THERMIONICS).

It has been mentioned that the photoelectrons produced by a given wave length of radiation emerge with a distribution of kinetic energies and velocities. At one time it was thought that the electrons inside a metal were practically at rest and that the distribution of energies among the photoelectrons was the result of collisions of the electrons with atoms of the solid in their escape. If the photoelectrons originate at the surface, another reason for their distribution of kinetic energies must be found.

According to the model pictured in fig. 2 the reason for a distribution of energies is the fact that before photoelectric absorption takes place the electrons possess different kinetic energies. If all electrons absorb the same energy, $h\nu$, and if all suffer the same energy loss, w, in escaping from the metal, then the distribution of kinetic energies of the photoelectrons is an accurate replica of the distribution of the kinetic energies of the electrons in the metal.

A comparison of the theoretical and experimental energy distributions of the photoelectrons from a sodium surface is shown in fig. 4. The agreement between the curves is particularly good for the most energetic electrons and provides a direct test of the

Fermi-Dirac distribution function which is used to describe the variation with temperature of the kinetic energy of the electrons in metals. The differences between the experimental and theoretical curves at low energies may be due to a slight velocity-dependent reflection of the escaping electrons by the surface potential.

FIG. 4.—ENERGY DISTRIBUTION OF THE PHOTOELECTRONS FROM SODIUM. THE WAVE LENGTH OF THE RADIATION IS 3,650 Å; TEMPERATURE OF THE SURFACE, 25° C.

The photoelectric effect of contaminated metal surfaces has been studied in great detail. Many of these surfaces have high yields and very low work functions. They are, therefore, of great importance in the manufacture of commercial photocells. The properties of a surface which is widely used, known as the cesium-on-silver oxide surface, are almost entirely unexplained. The threshold is in the infrared near 12,000 Å and the yield is extremely large over the visible and near ultraviolet regions of the spectrum. An antimony-cesium alloy is also used for commercial photocells because of its high and stable sensitivity to visible and ultraviolet radiation.

2. Insulators.—The topics of interest in the investigation of the photoelectric effect with dielectric solids are somewhat different from those with metals. Little work has been done upon the emission of photoelectrons from surfaces of insulators. The loss of electrons leaves the surface with a positive charge which prevents the establishment of a steady photocurrent. (*See* also INSULATING MATERIAL [ELECTRICAL].)

Whereas the photoelectrons produced in the interior of a metal cause an unobservable change in its conductivity, the decrease in resistance of an insulator due to the presence of photoelectrons is readily detected. This phenomenon is referred to as photoconduction.

Typical insulating crystals, such as the alkali halides and the oxides of the light metals are quite transparent to visible and near ultraviolet radiation. Absorption by the electrons starts somewhere in the ultraviolet. The typical absorption spectrum begins with a series of overlapping bands which are absorption lines broadened by the interaction of the electrons with the vibrating ions of the crystal lattice. Following these bands and overlapping them is a region of continuous absorption resulting from the photoelectric production of free electrons. In this region of the spectrum the absorption is so large that the radiation penetrates only a thin layer of material as in a metal. Experiments with photoconduction are usually performed with radiation absorbed in the long wave-length tail of the first absorption band.

In this case one cannot predict unambiguously whether photoconduction will result.

The reason for this statement is that absorption in the bands which precede the region of continuous absorption does not lead directly to the production of a free electron in the interior of the solid.

The electron is raised by the absorbed quantum to an excited state in which it is still bound to the positive charge left on the atom from which the electron originated. The electron and positive "hole" are not bound to an individual atom of the crystal but may move as a pair throughout the volume of the solid. The movement of this pair, or exciton, as it has been called, cannot lead to a shift of electrical charge and photoconduction. The exciton may obtain sufficient energy from the vibrating ions of the lattice, however, to enable it to dissociate into a free electron and a free positive charge.

In an electric field they may then move in opposite directions giving rise to a photocurrent. The temperature of the crystal determines the average energy of the vibrating ions and it is to be expected that if photoconductivity occurs because of thermal dissociation of excitons, it will disappear at a sufficiently low temperature.

Absorption of radiation in the long wave-length tail of the absorption band of an alkali halide crystal such as sodium chloride does not produce photoconductivity. Presumably the excitons are not thermally dissociated. Under the same conditions, photoconductivity is produced in the silver and thallous halides. In this case the question has been raised as to whether the absorption is not due to foreign impurity atoms.

Large quantum yields, approaching one electron freed for each quantum absorbed, are quite common. In the region of true continuous absorption and the direct production of photoelectrons, the measured yield becomes small. In the cases of diamond and zinc sulfide the photoconductivity disappears entirely. The reason for this is not understood but may, in some cases, be due to the two following effects. When the absorption coefficient becomes large the reflectivity of the crystal surface becomes large. The major fraction of the radiation does not enter the crystal, an effect which has been commonly overlooked. In addition, since the radiation is absorbed in a very thin layer at the surface, the concentration of photoelectrons is large and recombination is promoted.

The fate of a photoelectron in a crystal is a matter of interest. Through collisions with the lattice ions it rapidly loses the energy gained from the absorbed quantum and comes into thermal equilibrium with the lattice. Finally, it will recombine with an atom which has lost an electron or will be trapped at an impurity atom, a crack, or other imperfection of the lattice.

It appears to be the rule rather than the exception that the photoelectrons in the interior of the crystal initiate secondary reactions. These may be of the most diverse types and have complicated enormously the study of the primary photoeffect. It is commonly observed that the primary photocurrent produces a more or less permanent decrease in the resistance of the crystal. In a few cases it has been possible to study this secondary current independently of the photocurrent proper.

The problem is further increased in complexity by the unavoidable presence of minute amounts of impurities. Concentrations of impurities of a few parts per 1,000,000 may determine completely the observed effects, either by acting as sources of photoelectrons or by trapping them and giving rise to secondary reactions.

An example of the last-mentioned effect is found in the silver halides. The formation of the latent image in photographic emulsions is the result of the production of photoelectrons in the interior of the small crystals of silver halide which are dispersed throughout the gelatin of the emulsion. The photoelectrons are trapped at specks of silver sulfide which are present as impurities on the surfaces of the crystals. The silver halide has a small number of positively charged silver ions wandering throughout the interstices of the crystal lattice and these are attracted to the trapped electrons.

The electrons and silver ions unite to form silver atoms. Submicroscopic clumps of silver atoms form the latent image which makes the silver salt susceptible to development by the proper chemical reagents.

Photoconductivity is a general property of semiconducting solids. Semiconductors have a feeble, temperature-dependent, electronic conductivity which disappears at low temperatures where they become good insulators. The photoconductive properties of selenium and cuprous oxide have been known and used for many years. The pure elements silicon and germanium are semiconductors that exhibit photoconductivity when exposed to radiation whose wave length is less than 1.2 microns (μ) and 2 μ, respectively. One micron equals 10,000 Å. These threshold wave lengths correspond to the onset of strong optical absorption by the elements. The semiconducting compounds lead sulfide, lead selenide and lead telluride are extraordinarily sensitive to near infrared radiation when properly prepared in the form of thin films. Lead sulfide films are formed by vacuum evaporation followed by sensitization with oxygen or by chemical deposition from solution. Lead sulfide is a useful photoconductor for wave lengths less than about four microns, while the threshold wave lengths of lead tel-

luride and lead selenide are near six microns and eight microns, respectively. Lead sulfide cells are commercially available and have numerous industrial and military applications. The military applications include not only infrared signaling but also the location of vehicles and personnel in the dark.

Trucks, tanks, ships, planes and missiles can be detected at long ranges by means of the infrared radiation emitted by heated parts or exhaust gases. Infrared radiation in the form of body heat of soldiers has been used in their detection at night. Infrared search systems offer better optical resolution and less susceptibility to enemy jamming than do radar systems.

Cadmium sulfide is commercially important for the manufacture of photographic light meters and similar devices because of its stable characteristics and high sensitivity to visible radiation.

3. Gases.—The photoelectric effect in gases is of particular interest because the ejection of an electron from a free atom represents the simplest photoelectric process. Unfortunately, experimentation in this field is very difficult. The work necessary for the removal of the most weakly bound electron from the atoms or molecules of the simple gases is large enough to place the photoelectric threshold in the neighbourhood of 1,000 Å. In this region of the spectrum there are available neither convenient high-intensity radiation sources nor simple optical instruments. Common difficulties are the emission of electrons from the walls of the reaction vessel by scattered radiation, and the occurrence of secondary chemical reactions which are induced by the primary photoelectric effect.

The photoelectric threshold frequency can be predicted very precisely from spectroscopic observations. Photoelectric emission of electrons from atoms or molecules which have been previously excited by absorption of a quantum frequently gives an apparent threshold at a lower frequency than the predicted one. While the available data are in qualitative agreement with the theoretical prediction that one electron is emitted for each quantum absorbed, a precision test of this point is lacking because of the experimental difficulties. (*See* also LUMINESCENCE.)

4. Photovoltaic Effects.—The photovoltaic effect consists in the generation of an electromotive force in a material on illumination. An electromotive force (e.m.f.) is the source of the electric field which produces a current in a closed circuit of conductors. The discovery of the phenomenon by Becquerel is mentioned in the *Historical Survey* section of this article. A similar effect was noted in 1876 by W. Adams and R. Day, who observed the generation of an e.m.f. on illumination of a junction of selenium and platinum.

The junctions of semiconductors and metals which exhibit a photovoltaic effect usually possess the property of being rectifiers. That is, the resistance of the junction depends upon the direction in which current is passed through the junction. Two of the most important junctions of this type are the selenium-metal junction and that between cuprous oxide and copper.

A theory of the photovoltaic effect at such junctions given by N. Mott appears to be at least qualitatively successful. In the case of the cuprous oxide unit there is a film, termed the blocking layer, of pure oxide of the order of a ten thousandth of a centimetre in thickness separating the copper and the impure bulk oxide.

The bulk oxide owes its semiconducting properties to the presence of an impurity which is an excess of oxygen. When radiation is absorbed in the oxide near the blocking layer, electrons are ejected from the oxide into the blocking layer. Within the blocking layer, there exists an electric field which drives the electrons to the metal. This results, in a closed circuit, in the production of a steady current. The field in the blocking layer exists because of the trapping of electrons from the copper by the impurities of the cuprous oxide, giving the oxide a negative charge with respect to the metal.

The cuprous oxide-copper photocell has a threshold in the neighbourhood of 14,000 Å and a maximum sensitivity near 6,000 Å. Another commercially important photovoltaic cell is that formed from the junction of a metal and selenium. Its characteristics are much like those of the cuprous oxide cell (*see* SELENIUM CELL). These cells are extremely convenient for many applications since they generate their own power and operate without the use of batteries or power supplies. The electromotive force generated by moderate illumination is sufficient to operate a low-resistance microammeter. Their stability is inferior to that of vacuum photocells. In addition, when amplification of the small e.m.f. is necessary it is an extremely difficult matter. The response to changes in illumination is slow so that the cells cannot be used for many applications.

The chief field of application is the qualitative detection of radiation and measurements where high precision is unnecessary, as in light meters for photographic work. In photometric work of this type, the fact that the relative sensitivity of these cells to light of different colours is similar to that of the human eye is of particular importance.

A photovoltaic effect is produced when radiation is absorbed near a P-N junction (*see* TRANSISTOR) in a semiconductor. Excellent photovoltaic cells have been constructed with silicon, germanium or indium antimonide as the semiconductor. The P-N junction is formed by adding to the pure semiconductor carefully selected impurities with the proper spatial distribution. Arsenic and boron are typical impurities used with silicon. The silicon crystal is prepared so that there is an abrupt transition from a region in which boron is the dominant impurity to an adjacent region in which arsenic is the dominant impurity. At the junction of the two regions there is a large electric field that accelerates free electrons produced by absorption of radiation. Silicon photovoltaic cells have an output voltage of approximately 0.5 and a threshold wave length near 1.2 μ. They are efficient converters of solar energy to electrical energy. Their conversion efficiency is about 10%, approximately half their theoretical efficiency. Silicon solar cells provided electrical power for a radio transmitter of the first U.S. earth satellite, launched March 17, 1958. The Mariner 2 probe used 10,700 solar cells to operate its instrumentation and transmit data a distance of 36,000,000 mi. to earth as it passed Venus on Dec. 14, 1962.

P–N junctions in germanium are used to make photodiodes and phototransistors which (because of their fast response, high sensitivity and tiny size) have important applications for the automatic control of machinery, the sorting and counting of manufactured articles and the operation of high-speed computers.

IV. APPLICATIONS OF THE PHOTOELECTRIC EFFECT

The applications of the photoelectric effect are numerous and diverse. The ionization chamber which has been described is a standard instrument for the determination of X- and γ-ray intensities. The determination of X-ray dosage in medical therapeutic work is performed in this manner.

The photoelectric cell illustrated in fig. 5 (A) makes use of the emission from a metal surface. Frequently the metal surface is present in the form of a thin film which is deposited upon a portion of the inner surface of the glass envelope. The photoelectrons are drawn to the collector by an electric field and the resulting electric current measured with a galvanometer. Some photocells are not evacuated but are filled with a relatively inactive gas such as argon. The photoelectrons on being accelerated to the collector dislodge electrons from the argon atoms. In this manner the total current set up in the photocell may be 10 to 100 times the initial photocurrent. Since the photoelectric cell is inherently a high-resistance device, it is adapted for use with vacuum tube amplifying circuits. This is fortunate since the maximum current ob-

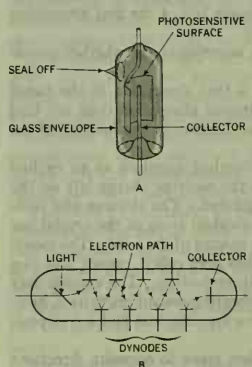

FIG. 5.—(A) PHOTOCELL. (B) DIAGRAMMATIC SKETCH OF PHOTOMULTIPLIER TUBE

tainable from a typical photocell is only of the order of a microampere.

To avoid the use of amplifying circuits the photomultiplier tube has been developed. This tube is illustrated in fig. 5 (B). In this device the photoelectrons are accelerated to the first of a set of auxiliary electrodes called the dynodes. The surfaces of the dynodes have the property of liberating several electrons for each electron which strikes them. In this manner the initial photocurrent is amplified as it passes from dynode to dynode. Such a device may have as many as ten dynodes and the current to the collector may be 100,000 times the primary photocurrent. The photomultiplier tube is manufactured in a size no larger than the ordinary photocell.

The scintillation counter is a device for the detection of γ rays or high-energy nuclear particles. A γ-ray photon or particle strikes a luminescent crystal and produces a brief flash of luminescence. A typical crystal is sodium iodide containing a trace of thallium as impurity. The photons of the luminescent radiation strike the cathode of a photomultiplier tube and eject photoelectrons that are amplified by the tube. If, as is commonly the case, the nuclear particle loses all its energy within the luminescent crystal, the number of luminescent photons and the magnitude of the output pulse of charge from the photomultiplier are a measure of the energy of the particle. The scintillation counter not only can detect and measure the energy of individual nuclear particles and γ-ray photons but does so in an incredibly short time. The speed of response of the counter is usually less than a microsecond and with crystals such as trans-stilbene may be as short as 0.006 microseconds.

The fundamental use of a photocell is to convert a change in the intensity of the incident radiation into a change in an electric current. This change in electric current may then be used to operate control or measuring devices. For example, a person approaching a doorway may interrupt a light beam which is incident upon a photocell. The abrupt decrease in photocurrent may be used to start a motor which opens the door or rings an alarm. The variations upon this usage are endless. In the manufacture or processing of materials photocells are used to detect imperfect articles and to actuate mechanisms which reject them. The speed and accuracy of such control is far greater than possible with a human operator.

In the production of sound motion pictures, a strip of variable density upon the photographic film is converted by a beam of light and a photocell into a fluctuating electric current which after amplification operates the loud-speakers. (*See* MOTION PICTURES.)

In television production the photoelectric effect is used to convert the light reflected from the object to be televised into an electric current. The electric current is reconverted by the radio transmitter into the long wave-length radiation termed radio waves. These are picked up by the receiver, transformed into electrical impulses and finally appear as a picture upon the fluorescent screen of a cathode-ray tube. (*See* TELEVISION.)

In scientific work photocells are used whenever it is desired to measure the intensity of a light beam with precision. They are, therefore, much used in the construction of photometric instruments. (*See* PHOTOMETRY.)

Finally, it should be noted that the photographic film, whose importance need not be reviewed, owes its light-sensitive properties to the production of photoelectrons by light in the interior of the silver halide crystals of the emulsion (*see* PHOTOGRAPHY).

V. NUCLEAR PHOTOEFFECTS

J. Chadwick and M. Goldhaber discovered in 1934 that the deuteron, the nucleus of the deuterium atom, will absorb a γ-ray quantum and disintegrate. The disintegration products are a proton and a neutron. The proton is the nucleus of the hydrogen atom of which deuterium is an isotope. The neutron is an uncharged particle of approximately the same mass as the proton. A minimum quantum energy of 2,170,000 ev (2.17 Mev) is necessary to produce the photoelectric disintegration of the deuteron. The nuclei of many other atoms have been shown to exhibit a similar reaction. In all cases the photoelectric effect results in the ejection of a neutron.

A second important nuclear photoeffect is pair production. A γ-ray quantum in traversing the neighbourhood of a nucleus may be annihilated and a positive and a negative electron created. This is a direct conversion of radiant energy into matter in which energy and mass are related by an equation due to Einstein:

$$E = mc^2, \qquad (4)$$

where E represents the energy converted into the mass m, and c is the velocity of light. With m taken as the sum of the masses of the positive and negative electrons, the minimum quantum energy E which is necessary for pair production is calculated as 1,020,000 ev. A quantum of greater energy will impart kinetic energy to the created electrons. This process is one of the most important mechanisms by which high-energy quanta interact with matter. The positive electron is unstable and soon after its creation combines with a negative electron, the pair being annihilated with the creation of one or two γ-ray quanta.

The γ-ray photons whose energy exceeds 150 Mev interact with protons and neutrons to create positively charged (π^+), negatively charged (π^-) and neutral (π^0) mesons. The charged π mesons have the same charge as that of an electron but have a mass that is 273 times that of the electron mass. They are unstable particles that decay into μ mesons and neutrinos with a lifetime of 2.6×10^{-8} seconds. The neutral π meson has a mass that is 264 times the electron mass and disintegrates into a pair of γ-ray photons in about 10^{-15} seconds.

The interaction of a γ-ray photon with a proton may either transform the proton into a neutron with the creation of a π^+ meson or create a neutral π^0 meson and leave the proton unchanged. Similarly, the interaction of a γ-ray photon with a neutron may produce a proton and a π^- meson or create a π^0 meson without transformation of the neutron into another particle.

Pairs of π mesons and of μ mesons are also created by the interaction of γ-ray photons of sufficient energy with nuclear particles. Since it is believed that mesons are responsible for the forces between nuclear particles, they are the subject of intensive research.

PHOTOENGRAVING, the photomechanical procedures by which an illustration with a relief printing surface is produced for use in the letterpress printing process. Although the term was originally applied exclusively to etched metal printing plates on which an image was obtained by photomechanical methods, photoengraving has come to be applied broadly to the making of letterpress relief printing surfaces in zinc, magnesium, and copper or in plastic or photopolymeric materials (photosensitive plastics), and to printing plates made by one of the electromechanical platemaking machines. Many of the physical and optical bases for photoengraving are identical with those employed in the offset lithographic or gravure platemaking operations. (*See* also PRINTING; LITHOGRAPHY; GRAVURE.) This article is arranged in the following sections:

I. HISTORICAL DEVELOPMENT

The use of illustrations is as old as printed and written text. Photoengraving is the oldest of the engraving techniques employing photomechanical methods, since the printing process it serves, letterpress, was in existence for more than 300 years before other processes were developed.

Although printed illustrations appeared as early as the 15th century, the first engraving made by the action of light on a photosensitive plate is reported to have been that of Joseph Niepce (1826), a Frenchman, who coated a metal plate (either pewter or copper) with photosensitive asphalt, and under bright sunlight printed the image of Cardinal Georges d'Amboise from an etching which he used as a positive image. He then developed and etched a relief image on the metal surface. Niepce's discovery may have been of historical importance, but it did not bring an immediate use of photoengravings for printed images. Many other experimenters in Europe and the United States made further attempts at producing engravings, but the origin of the modern engraving process rested in the discovery by Mungo Ponton (1839) of the light sensitivity of chromium salts. However, Ponton was not an engraver and apparently was not interested in this field. The work of Firmin Gillot in Paris appears to have given the greatest impetus to engraving on zinc, although none of the early experimenters employed photography to produce the printing surfaces. In fact, much of the work antedated photography.

The discovery of the wet-collodion process for photography provided the means for producing the photographic negative as the basic element in photoengraving. Frederick Scott Archer introduced this process about 1850. The technique also provided a method of stripping or removing the image from the glass photographic plate. The wet-collodion process was used extensively by process photoengravers until the introduction of commercially coated stripping film in the 1930s. Thereafter, its use gradually declined because of the greater convenience and lower cost of the ready-made stripping films.

W. H. Fox Talbot, in England, appears to have been responsible for the direct application of the dichromated colloid to photoengraving (1852). He was interested in gravure images, but he learned of the light-hardening effect of dichromated gelatin in this work, and use of this information in other applications followed naturally.

It was obvious to Talbot and other experimenters that, if the reproduction process was to succeed, a means of breaking up the continuous-tone images in photographs or drawings, and reproducing them in quarter, half, and three-quarter tones, had to be found. Since the letterpress printing machine provides a uniform coating of ink on the printing surfaces, no provision can be made for reproducing intermediate tones between black and white in an illustration by varying the thickness of the ink film laid down by the press. Therefore, some other means of producing this effect had to be found. The answer, of course, lay in the halftone process, in which grays are obtained by varying the size of halftone dots and thus controlling the amount of ink laid down in a given area. However, as in the case of so many developments, credit for the invention of the halftone technique cannot be attributed to any individual; the work was evolutionary.

A single-direction line screen in which parallel lines were scratched in an opaque background is described in a French patent of 1857. As early as 1869, William A. Leggo, a Canadian, produced an image with a crossline halftone in the *Canadian Illustrated News*. Later, in 1882, Georg Meisenbach, using a single-direction screen, produced a crossline halftone by making half the exposure with the screen in one position and half with the screen rotated 90°.

Frederic E. Ives, who in 1885 prepared a mechanically ruled crossline screen on film, was responsible for the optical explanation that led to modern screens. There were others who made screens by various means, but the brothers Max and Louis Levy (1893) were the first to succeed in producing commercial grades of screens. The Levy brothers coated selected plates of high-quality optical glass with an etch-resistant base in which parallel lines were cut by a ruling machine. The ruled lines were etched with hydrofluoric acid and filled with an opaque material, after which they appeared in sharp contrast with the unetched glass. Two ruled glass plates were then cemented face to face with the lines at 90°, sealed, and bound in a metal frame.

1. Halftone Screens.—In principle, at least, there has been no significant change in the making of glass halftone screens from the methods used by the Levy brothers. Other screen patterns, such as the grainlike mezzograph screen, have been tried but none has produced such consistently good results as the halftone process. Halftone screens may be obtained with line frequencies of from 40 to 400 lines per inch. The coarser screens are used for illustrations printed on rough papers and the finer ones for illustrations of higher quality on high-finish and coated papers. The 50-, 60-, 65-, and sometimes 85-line halftones are generally used in newspaper reproduction, while 100-, 110-, and 120-line halftones are suitable for supercalendered papers and for the text papers used in some magazines; they find wide application for single-colour illustrations and for some multicolour work on these papers. The 120-, 133-, and 150-line halftones are usually used for colour illustrations in magazines and books printed on coated papers where picture detail is important. The 175- and 200-line photoengravings are seldom used because of the difficulties in keeping ink from filling in the plates during the press run. These fine rulings do, however, find some application in offset lithographic printing.

Although the production of glass screens has not changed greatly since the initial work of the Levys, there have been many other changes in the application of the halftone screen to photoengraving. Among the most important was the introduction of the contact screen. This is a film material containing an image of the pattern produced by a glass halftone screen. In use, it is held in contact at the focal plane of the camera or enlarger, directly over the film onto which the image is printed, and the exposure is made while contact is maintained. This eliminates certain diffraction effects inherent in glass screens, frees the operator from some of the lens diaphragm restrictions imposed by glass screens, and eliminates the necessity that lens opening, screen distance from the focal plane, and screen ruling be in proper relationship.

Contact screens are made with a silver (gray) screen image and with a magenta dye image; the dyed screen gives some additional control over halftone negative quality through the use of colour filters on the camera.

2. Special Effects.—Such techniques as dropping out the highlights from the halftone negative (*i.e.*, eliminating the dots in these areas) in order to achieve increased contrast in illustrations were studied and introduced by several individuals. F. J. M. Garland patented such a method in 1883, and in 1925 Laurent Bassani introduced a camera attachment that made it possible to impart a slight motion to the image on the film and thus reduce exposure to the point where small highlight halftone dots were not printed or developed. However, the most successful of the highlighting methods were those employing fluorescence phenomena. Walter Marx in 1938 patented his fluorographic process, in which fluorescing materials were incorporated in the artist's pigments. Alexander Murray patented similar pigments in 1935 and 1938 designed for colour correction in water-colour illustrations. The Kemart process, introduced shortly thereafter, utilized a fluorescing paper board. All of these processes were based on the same procedure: making an exposure under normal lighting for over-all reproduction, and then making an additional correcting exposure under ultraviolet light. The fluorescence produced by the ultraviolet illumination provided additional exposure in the affected areas that gave the necessary correction for highlighting or colour correction.

3. Process Developments.—The discovery of the halftone

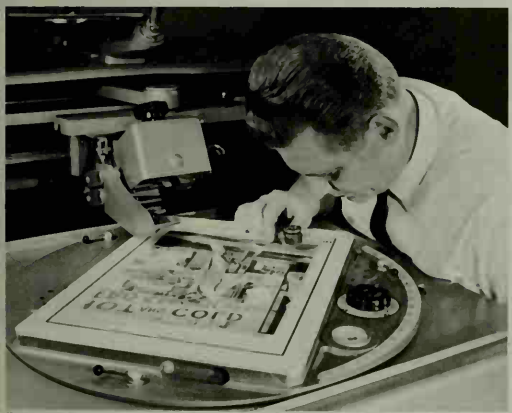
In producing a photo-engraving plate, the subject is first photographed through a halftone screen so that the image is divided into a great number of small "dots." Here the cameraman is positioning copy in a pressure frame that will be tilted so that the copy is held vertically when it is photographed by the process camera in the background

PLATE MAKING

An engraver adjusts an exposed plate in an etching machine holder. The plate will then be splashed with an etching bath. The modern technique of etching produces good plates without the use of dragon's blood etching powder, once generally used to prevent undercutting the printing surface

A power router is used to cut out nonprinting areas of the plate. The router does not disturb fine edges already cut by hand tooling

To make colour proofs, the finished yellow, red, blue and black plates are placed on a high-speed power proof press which prints the four colours "wet" in rapid succession



The halftone plate is inspected to determine if the plate has been etched to the proper depth. If the depth is too little, the space around the dots will fill up with ink during printing. This plate is shown on an engraving machine called the Vario-Klischograph, which can be adjusted to enlarge or reduce the copy and to select a variety of halftone screens. This machine eliminates camera work, etching and hand finishing

The PDI scanner, an electronic machine made by Printing Developments, Inc., a subsidiary of Time, Inc., makes colour-separation negatives from a colour transparency in one operation. Here the operator inserts a photographic transparency of a colour subject into the scanner

PHOTOGRAPHED ESPECIALLY FOR ENCYCLOPÆDIA BRITANNICA, INC.

PHOTOENGRAVING

COLOUR PRINTING BY FOUR COLOUR PROCESS

PHOTOGRAPH, ENAT FROM THREE LIONS

Reproduction of a painting, a photographic transparency or such subjects as wood grain and fabric is accomplished by the halftone colour process—a photomechanical technique which has replaced tedious and expensive hand engraving. The reproduction may be either larger or smaller than the original. The first step in making four-colour printing plates from the Ektachrome transparency at left above is to make colour-separation negatives by means of colour filters on the camera, as indicated in the diagram. When the transparency is photographed through a blue-violet filter, only the complementary colour—yellow—is reproduced in the negative. Green, orange-red and pale yellow filters are used to photograph the images of the red, blue and black values in the transparency. When printing plates (metal positives) are made from the photographically-produced separation negatives, each contains the image of the single colour it represents. The plates are printed in the sequence shown (top to bottom) above. The final black "key plate" provides sharp detail

screen was primarily responsible for the development and growth of photoengraving, and this growth was directly affected by other developments related to the printing industry. The introduction of the first practical colour film for amateur and professional use, Kodachrome, in 1935 probably did more to accelerate printing developments than any single invention. It made a colour studio out of the entire world and greatly increased the use of coloured illustrations. At approximately the same time, the commercial production of on-the-machine coated paper and heat-drying printing inks for letterpress printing began. Many colour developments related to films, printing processes, and materials followed.

Electrolytic and Powderless Etching.—Although the etching of metals by chemicals was the obvious method of producing printing plates, Henry Mawicke of Chicago was among the first (1912) to apply the electrolytic principle, utilizing the plate being etched as the anode in an electrolytic bath. The electrolytic etching machine is still used for specialty work, but it never found widespread acceptance.

Early methods of etching zinc and copper—methods that are still in use in many areas—were tedious, inexact, and could be learned only by trial-and-error training. The principal difficulty lay in achieving sufficient vertical etching depth without encountering undue lateral etching, which would undercut the edges of the halftone dots and lead to their collapse on the printing press. Some success in overcoming this problem was achieved through "powdering," in which an etch-resistant resin was deposited around the sides of the dots, permitting further etching in depth. The method did not, however, give consistently satisfactory results. A major step toward solving the problem—in fact, the most important development in the field of etching since photoengraving was invented—came in the Dow-Etch method, a means of etching a magnesium plate without the use of powder, introduced in the U.S. by the Dow Chemical Company. Experimenters found that by adding an oily material and a surface-active (wetting) agent to the nitric acid bath, and controlling the conditions under which the plate was etched, they could produce characters in relief with adequate etching depth and virtually no printing area loss during the etching. The process was later adapted to the etching of zinc, and was quickly adopted by engravers in all parts of the world.

With this major hurdle overcome in the etching of zinc and magnesium, attention turned to copper. Rexford Jones, working for a group of photoengravers carrying on developments under the name Photoengravers' Research Institute, found that a powderless etching process for copper was possible when thiourea was added to the iron chloride etching bath. He obtained a patent in 1956. His work was followed by further refinements in the process and the introduction of new compounds to add to the etching bath.

Electromechanical Platemaking.—While these developments in chemical etching were taking place, other experiments were conducted to assess the feasibility of replacing traditional methods with the techniques of electronics, optics, and mechanics. The first successful result of these efforts was the Scan-A-Graver, introduced in 1947, which optically scanned a picture and simultaneously reproduced it as a relief printing plate on a plastic sheet. The Scan-A-Graver found wide application, particularly in newspaper plants where photoengraving procedures were time-consuming and therefore costly. Within a short time, machines were developed that were capable of making etched plates in metals.

Meanwhile, investigators at the du Pont laboratories in the U.S. discovered about 1950 that some methacrylate compounds could be quickly polymerized by exposure to light. Nylon was also found to have photosensitive properties, and by 1958 both materials were being offered for use in printing plates.

Wraparound Plates.—A significant improvement in letterpress printing techniques came with the development of the wraparound plate, a thin metal or plastic sheet on which an entire printing form is photoprinted and etched. In appearance and in use the wraparound plate is much like an offset lithographic plate. Because it permitted letterpress printing with a relatively inexpensive but high-speed rotary press, the wraparound plate was particularly advantageous for smaller printing plants, which previously had to rely on slower flat-bed presses for letterpress work.

The term wraparound is generally associated with the thinner flexible metal or plastic-coated metal plates affixed to the press cylinder by clamping devices. A second type of photoengraved printing plate is prepared by etching an image on heavier precurved materials, varying in size from single page forms to several pages on a single plate.

Wraparound plates require an etching depth of approximately 0.01 to 0.015 in. on plate material 0.025 in. in thickness. The precurved printing plates have thicknesses of 0.032 to 0.040 in. and etching depths up to 0.020 in. Rigid plates are affixed to press cylinders by small clips. Therefore, plates of this thickness, as well as some wraparound plates, are completely engraved in curved form, a procedure that also insures accurate colour register and image length.

II. MODERN ENGRAVING TECHNIQUES

Plates made by the photoengraving process are all relief letterpress printing plates, but they may be further classified into groups on the basis of the materials from which they are made or the types of images they are to reproduce. Photoengravers classify them as zinc, magnesium, copper, or plastic plates; the plastic plates may be those produced either from the photopolymeric plastics or by one of the electromechanical engraving machines.

Buyers of printing commonly classify engravings in terms of cost, and such a grouping includes, in ascending order of costs: line engravings, halftone engravings, combination line and halftone engravings, single-colour, two-colour, and duotone engravings, and process colour plates. Each of these types may be produced in any of the customary metals or plastics. Process colour plates are usually made of copper in the U.S. and U.K., and of zinc elsewhere.

A. Basic Production Processes

The essential operations for the production of all types of photoengravings are similar. They include photography, photomechanical operations, etching, finishing, routing, blocking, and proofing.

1. Camera and Darkroom Equipment.—The engraver's camera, called a process camera, is a rigidly built machine designed to allow precise positioning of the lens and copyboard so as to provide control over the enlargement or reduction in size of the copy. It has a colour-corrected lens designed to give the sharpest possible image when focused on a plane surface, without the distortions commonly found (though usually unnoticed) in the average portrait or amateur camera lens. Process cameras are designated as gallery or darkroom types. The gallery camera may be installed in any convenient location, but all film must be removed in a light-tight cassette and processed in a separate darkroom. The darkroom camera is installed with its film holder as an integral part of the darkroom wall, giving easy access to the darkroom facilities.

Virtually all photographic work is done on film coated with high-contrast emulsions especially developed for graphic arts work. The introduction of dimensionally stable film bases has nearly eliminated the use of glass plates. The film emulsions used for halftones are of the "lith" type, giving the extremely high contrast needed for halftone or line reproduction. Stripping film, a laminar film with a soft adhesive layer between the base film and the emulsion layer, is widely used to permit images to be removed from the base film and properly oriented on the glass or film flat through which the metal plate will be exposed.

2. Plate Coating and Printing.—Photomechanical operations include cleaning the metal plate surfaces, coating them with a light-sensitive solution, drying the coating (known as the top or enamel), and making the exposure on this coating through the negative prepared in the earlier photographic step. Care is required throughout these operations to prevent imperfections such as bubbles, dirt, or scratches in the light-sensitive coating. The zinc, magnesium, or copper is prepared for coating by a careful cleaning with pumice and water. The light-sensitive coatings are usually poured over the surface and then the plate, held flat, is whirled to insure uniform coverage by the solution.

The light-sensitive coatings are usually a dichromated colloid

material, but light-sensitive resins are also used. The most common are called hot top and cold top enamels. Cold top enamels are used on zinc and magnesium, which cannot be heated because of their low recrystallizing temperatures. They are usually slightly alkaline solutions of shellac or polyvinyl alcohol to which a dichromate is added. Hot top enamels nearly always contain fish glue, as well as some egg albumin, to which is added a dichromate sensitizer. The mixtures of glue and albumin are used when it is necessary to control the etch-resistance and the ease with which the edges of the enamel break away during the etching process. Hot top enamels must be set at temperatures of 400°–600° F and therefore are used mainly on copper.

The tops are high-contrast materials that, when exposed to strong light, harden where the light strikes them and lose their solubility in water. Development in water then removes the coating from the unwanted areas of metal, exposing the metal to the etchant in the etching process. Photosensitive resinous materials find wide application in electronic circuit printing, an operation analogous to photoengraving (*see* PRINTED CIRCUIT). They have more limited applications in the making of photoengraved letterpress plates. These resinous materials are developed in organic solvents.

3. Etching and Finishing.—Nitric acid is commonly used in etching zinc and magnesium, the strength varying from 6 to 15% depending on the metal. Copper is attacked by some acids, but it is more readily attacked by ferric chloride (iron chloride) and this is the most common material used in photoengraving, usually in concentrations of 30° to 44° Baumé.

The etching may be done in an open tub or tray, but this method does not give the control needed for economical operation and is employed only where control is not critical. Most quality work is carried out in etching machines provided with agitators that break up the etchant into a spray and force it against the plate.

In the conventional etching processes, the acid or iron chloride is used without modification, although great care is needed to prevent overetching. In many cases, especially when making line plates, the etcher resorts to powdering to protect the upper printing areas from attack while he continues to etch in depth, but it is becoming more common to etch these plates by one of the powderless etching processes described earlier. Line plates are usually etched to depths of 0.010 to 0.045 in. Halftones may be etched to depths of 0.0023 to 0.009 in. depending on the fineness of the screen. Coarser screens are etched deeper.

The photosensitive plastic plates are not etched in the ordinary sense. They are washed out with either dilute alkali or alcohol. Overetching is not a problem with this type of plate.

Finishing includes hand operations to remove imperfections in the image area of the plate, and to improve its outward appearance. In colour plates, finishing also includes colour correction, a process of further etching or burnishing selected areas to improve fidelity of reproduction. Finally, unwanted metal in the nonprinting areas of the plate is removed by a mechanical routing machine.

4. Blocking and Proofing.—Blocking consists in adhering the plates to cherry-wood blocks to bring the printing surface to type height, 0.918 in. Until the development of thermoplastic adhesives in the 1940s, blocking was always done by nailing the plates to the wood blocks. This tedious and costly operation was largely replaced by hot-mounting of the metal plate. First the plate is placed on a block of wood precoated with adhesive and then this sandwich is subjected to heat and pressure. Upon cooling, the plate sticks firmly to the block without need for nails.

Proofing consists in placing the plates on a precision press and taking sample impressions or proofs that will show how the plates will print during a regular press run.

B. Colour Plate Production

The first colour work in printed matter was produced manually —artists painted in the necessary colours on the black-and-white printed sheets. Later, stencils were used to speed this work and, in a further development, colours were printed—either as solids or tints—from hand-engraved plates. All of this work, however, was crude by modern standards, and nothing approaching four-colour process printing was possible.

Modern colour printing, done with either three or four plates, each using a different colour of ink and overprinting the others, is based on the subtractive system of colours; *i.e.*, any intermediate hue can be obtained by some combination of two or more of the subtractive or secondary colours. The best colour printing is usually done with four colours: yellow, magenta (blue-red), cyan (blue-green), and black. The black plate is used to provide added uniformity of colour rendition and to maintain the detail in the picture. In theory, black should result whenever the three subtractive colours are superimposed. Thus, it should be possible to produce black wherever all three of the secondary colours are present without affecting reproduction. Further, any reproduction theoretically could be obtained by using only black plus the proper two of the secondary colours. However, this has not been found practical because of the nature of printing ink pigments and the lack of complete precision in the printing operation. Consequently, it is common practice to use the black plate to supplement the colour plates, portions of which are allowed to print in all except pure white areas of an illustration. The colour plates and the black plate must be printed in register; *i.e.*, they must be superimposed so that identical portions of the image in each plate colour overprint each other.

1. Colour Separation.—In manufacture, the production of an individual colour plate involves the same steps used to produce an ordinary black-and-white engraving, once the image is printed on the metal. Prior to this, the only differences lie in the use of colour filters on the engraver's camera and in steps to reduce the contrast range of the copy (the contrast range of a photographic transparency may be as great as 300:1, while limitations in the printing process reduce the attainable range with paper and ink to about 20:1). The camera filters are the red, green, and blue filters for the colour negatives, and the yellow filter for the black negative. The blue filter produces the yellow negative, the green filter the magenta negative, and the red filter the cyan negative. Masking procedures such as those employed in other forms of colour print reproduction are followed to remove yellow values and magenta values from the blue and red negatives and thus correct for deficiencies in the printing inks and in the colours of the copy.

Colour plates are made by two general methods, the indirect and direct. The indirect method produces continuous-tone negative separations from which positive continuous-tone separations are prepared. These are film or plate transparencies. After the masking and other tone correction work has been done on them, the positive image is placed in a process camera with a halftone screen, and the screen negatives are produced. In the direct method, the screen negatives are prepared direct from the copy through the colour separation filters and a halftone screen onto a high-contrast panchromatic film or plate to produce a negative ready for transfer to the metal plate.

The proofing of halftone colour plates for wet printing on high-speed presses (when one colour does not have time to dry before the next is laid down) is a critical operation, for the proofing must be carried out under conditions simulating as closely as possible those that will be encountered on the production press. Specially built proof presses make this possible. In appearance they resemble four conventional units placed end to end, and the sheet of paper is passed in turn over the four plates. However, because the production press employs not the original flat plates but curved duplicates made from them, and because ink and paper specifications are highly variable, exact duplication of production results in a proofing operation is difficult.

2. Elimination of Moiré.—A serious problem in colour reproduction is the occurrence of an interference pattern or moiré caused by the overprinting of the screens in the colour plates (a similar effect can be obtained by superimposing two pieces of window screening or fine net cloth). Because it is impossible to maintain printing register within the degree necessary to avoid such an effect, it is common practice to rotate the halftone screen when making the negatives so that each of the four plates has its

screen pattern in a different position. The screens are placed so as to provide maximum separation in rotation between the black, magenta, and cyan screen angles, with the yellow screen positioned between two of the least troublesome colours. For example, the yellow screen may be set at 90°, the magenta at 105°, black at 45°, and cyan at 75°; here it will be noted that the lightest colour, yellow, is at the angle of maximum disturbance to the eye and the darkest colour, black, is at the angle of minimum disturbance. In three-colour reproduction, when black is not used, the cyan screen would generally be placed at the 45° angle.

A moiré pattern may also occur during wet colour printing if the inks are not performing properly. One expedient used to avoid this is to make the yellow plate with one screen ruling and the rest of the plates at another ruling; *e.g.*, the yellow plate with a 133-line screen and the magenta, black, and cyan plates with 120-line screens.

3. Colour Scanners.—Paralleling the development of the electromechanical engraving machine, experimenters in the U.S. and Europe produced several machines that automatically made corrected colour-separation negatives. In one of these, developed for Time, Inc., in the U.S., a photographic transparency wrapped around a transparent cylinder was scanned by a beam of light which then passed through a colour splitter and into a bank of photoelectric cells. Energy from these cells activated lamps that produced the colour-separation negatives on another drum attached to the same shaft.

C. Production Specifications

1. Line Plates.—In line illustrations all of the image areas are either black or white, and hence no halftone screen is required to copy them for use in making a printing plate. The negative is suitable as it comes from the camera to transfer the line image onto the metal.

Plate preparation, coating, burning-in, etching, and finishing are essentially the same as for halftone plates. However, certain specifications must be met. The nonprinting areas must be etched sufficiently deep to prevent the ink rollers from touching them on the press, and to prevent them from rubbing on the surface of colour sheets during wet colour printing. For presses with accurately adjustable ink rollers, the etch depth may be as little as 0.01 in., and the same depth is permissible in thin, wraparound press plates. For conventional printing presses, the minimum etch depth is about 0.02 in. Plates that are to be duplicated by electrotype or stereotype processes may require slightly greater depths, although normal etching ordinarily is sufficient to produce good duplicates. Plates from which rubber duplicates are to be made will require etch depths as great as 0.045 in.

2. Halftone Specifications.—Etch depths in halftone plates need not be as great as those in line plates, but the contour of the halftone dot and the depth of the etched areas are very important. Etch depth in highlight areas, the most critical portions of halftones, varies from 0.006 in. in a 65-line halftone to 0.002 in. in a 133-line engraving.

3. Combination Line and Halftone Plates.—These plates must be prepared by assembling, in the negative form, the halftone and the line portions of the illustration, and then, after transferring them onto the metal, etching them in two operations so as to attain the best results for both portions. Some workers have been successful in simultaneous etching of both parts of combination plates, but these are special cases and usually require a high degree of skill. However, the powderless etching processes permit easier etching of coarse-screen combination plates for use in newspapers. Combination line and halftone plates may also be produced by making two plates in separate operations and mounting them on a single block in proper position with respect to each other.

PHOTOGRAMMETRY is the use of photographs for measurements to be applied in such fields as map making and surveying (*see* Geodesy). In 1851 the Frenchman Aimé Laussedat first compiled map data based on measurements from photographs. Handicapped by the narrow field and imperfections of the photographic lenses of his time, Laussedat (known as the father of photogrammetry) and other workers made little practical progress.

Nearly 50 years after Laussedat's original conception of photogrammetry the first practical work was done by E. Deville, a Canadian who constructed maps by plotting intersections from phototheodolite pictures (*i.e.*, those taken from tripods on the ground). Deville also invented a simple machine for drawing maps from a stereoscopic pair of pictures. In the 20th century progress in photogrammetry was much more rapid. Practically all the development prior to World War I contemplated the use of apparatus for automatic plotting from phototheodolite pictures. Many machines of European origin were made for this purpose; these use a pair of pictures taken from the extremities of a measured base line. They mechanically plot the intersection of the light rays that formed the common images of the two pictures.

This terrestrial method was very successful and economical, especially in such mountainous regions as the Alps and in Alaska where the steep terrain afforded camera stations overlooking an extensive area. But photogrammetry changed abruptly with the introduction of practical aerial photography in World War I. The airplane afforded a superlative camera platform and flew rapidly from one exposure station to the next. Large areas could be covered in a single overlapping pair of photographs and blind areas (a serious handicap in the terrestrial method) were minimized.

Aerial photography also produced complications; in terrestrial work the length of the base subtending the two pictures is known, but not so in aerial photography. Other unknowns in aerial photography are the precise elevation from which the pictures are taken, and, especially, the difference in elevation between an overlapping pair of pictures and the angle of inclination of the camera at the instant of exposure. The stereoscopic plotting machines developed for terrestrial photography were replaced by universal plotting machines that used terrestrial or aerial photographs, and dominated most of the period between World Wars I and II. By 1945 terrestrial photogrammetry was used very little. Even large-scale maps of dam sites (for example, at 1:240) were produced by aerial methods. The quality was excellent, and the method proved economical. Emerging from World War II were aerial stereophotogrammetric processes, mosaics, and a once widely used reconnaissance mapping technique, the Tri-Metrogon system.

Ordinary aerial photographs have a wide variety of uses aside from photogrammetry; the airview (oblique photograph) employed for many illustrative purposes is the simplest and most widely understood application of aerial photography. Uncorrected vertical contact prints are extensively used, especially in petroleum geology. Hundreds of thousands of square miles of territory have been photographed for this purpose, to produce complete sets of stereoscopic, overlapping, vertical prints; usually with an index map that relates each print to the survey as a whole.

GEOMETRY OF THE PICTURE

Early users of aerial photography discovered that a picture taken with the camera axis vertical was truly a map only if the ground was flat and horizontal. Aerial pictures in those days were said to be distorted, partly from defects in the lenses used. The major trouble, however, was displacement; *i.e.*, the picture was a conic projection. Thus, vertical objects (such as telegraph poles) not at the exact centre of the picture appeared as radial images with base toward the centre and top displaced outward (fig. 1 and 2, *see* next page). The picture is a perspective with all vertical lines disappearing at a vanishing point at the centre. If there is a hill the same height as the pole (fig. 1), the top of the hill also will be displaced. However, since these displacements lie along radial lines, the angle subtended by any two images at the centre (the nadir point of the picture) is a true angle. Thus while this displacement is troublesome in trying to use an uncorrected contact print of mountainous terrain, it is the essence of photogrammetry. Actually photogrammetry measures this displacement, and all elevation data are derived from these measurements.

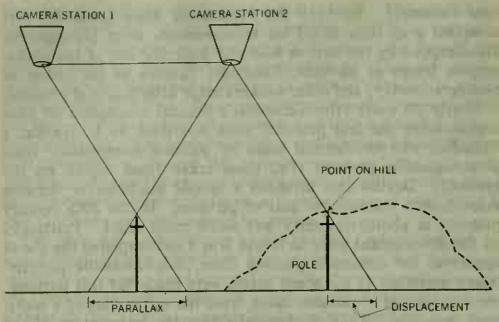

FIG. 1.—DISPLACEMENT IN OVERLAPPING PHOTOGRAPHS BECAUSE OF DIFFERENCE IN OBJECT HEIGHT AND PARALLAX (DISTANCE BETWEEN DISPLACED POINTS MEASURED PARALLEL TO AIR BASE)

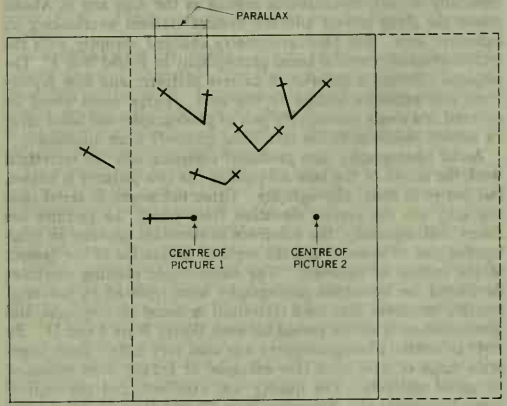

FIG. 2.—RADIAL IMAGES OF POLES OF SAME HEIGHT. PARALLAX THE SAME FOR THE SAME ELEVATION

The simplest form of stereoscopic plotting instrument measures the so-called parallax of the picture; *i.e.*, the measured difference between conjugate image points of objects at different elevations. Thus, if the two overlapping images of the base of a pole are placed in registry the images of the tops will be in two radially disposed positions. Their separation, measured parallel to a line connecting the picture centres, is the parallax of the top of the pole in relation to the base (fig. 2).

SYSTEMS OF CONTROL

All photogrammetric processes depend on ground control or office control. In ground control, positions or elevations (or both) are established independently of the aerial photography and the laboratory. Most ground control is by conventional survey on the ground, the most common methods being astronomical determination of position, triangulation, traverse and leveling (either by spirit level or trigonometric leveling), or radar (*q.v.*). Office operations are done in the laboratory by radial control methods, aerial triangulation, and mathematical solution.

Radar Control.—Horizontal and vertical radar control were in general use before the 1960s. Horizontal systems such as Hiran and Decca (*see* AIRWAYS; NAVIGATION) locate the airplane at the instant each photograph is taken. A radar signal is timed in transit between a ground station and the aircraft; this is translated as distance on dials carried aboard. The dials are photographed at the instant the main aerial camera is triggered. These systems work to extreme accuracy at distances of 100 mi. and often much farther. This method is, however, often unjustifiable because of its considerable cost. Vertical control is supplied by APR (airborne profile recorder), in which an impulse is reflected by the ground back to the aircraft. The altitude above the earth's surface is automatically plotted on graph paper; elevation is measured down from the barometric datum of the aircraft. Good accuracy may be obtained with this method of vertical control.

Aerial Triangulation and Bridging.—Aerial triangulation involves starting from some known ground control and extending by laboratory processes through a series of pictures. These processes are known as carrying forward control, or bridging. Control is carried forward by the successive adjustment of adjacent stereoscopic models upon each other. The stereoscopic model, for example, consisting of pictures 1 and 2, is adjusted to known ground control. Picture 1 is then replaced by picture 3, and while 2 remains unmoved in the plotting machine, 3 is adjusted to 2 until perfect stereoscopic correspondence is achieved. Then 2 is replaced by picture 4, and the process continues indefinitely. Closure errors that build up toward the end of a long series of pictures have to be adjusted.

Bridging is an office process of extending control between separated clusters of ground control and may be understood by examining how it is done with the multiplex (fig. 5). The multiplex is set up with as many as 20 projectors, each of which projects the image of one picture in the series. The first pair of projectors is adjusted to known ground control, and each subsequent projector carrying the next picture in the series is adjusted successively until control at the far end of the series is reached. The error of closure is distributed by formulae that consider the method, lens distortion, curvature of the earth, and similar factors.

Analytic Aerotriangulation.—In the early 1960s the graphical and machine bridging methods of control began to give way to mathematical analysis. By 1965 the best and most economical results were being obtained by measuring the picture and putting these measurements and other variables such as lens distortion, curvature of the earth, atmospheric refraction, and film distortion into a program for computer solution.

The Slotted-Template Method of Horizontal Control.—The most universally used method of office control was originally known as the Arundel method in England and the Bagley method in the U.S. A modern evolution, generally called radial control, is widely practised with both slotted cardboard templates and slotted metal arms. The slotted-template (templet) method, widely used in World War II for compiling maps when insufficient ground control existed, is a means of graphical triangulation. By this method (most easily explained in the cardboard version) a template is made from each individual photograph. The principal (nadir) point and at least eight office selected radial points around the edges are pricked through from the picture to the cardboard (fig. 3). A hole is punched at the centre prick mark of the template, and a radial slot is cut through each of the outlying points. Because of the conventional 60 × 30% overlap, each of these points is common to several pictures—sometimes as many as six. The templates are then "buttoned up" with connecting posts (studs) through the intersecting slots, so that all slots representing a common point from the pictures are assembled over a single post. Each post resembles a flatheaded rivet with a hole through the stem. The known ground-control points are shown on the photographs and on the templates representing these photographs. The

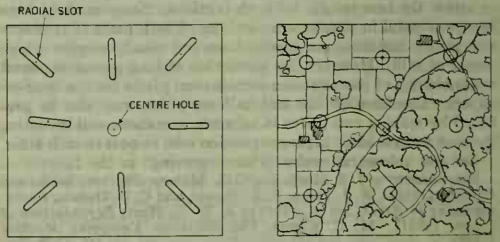

FIG. 3.—A SLOTTED TEMPLATE IS MADE FROM EACH PHOTOGRAPH. THE ASSEMBLED OVERLAPPING TEMPLATES CONFORM IN A GRAPHICAL TRIANGULATION NET

positions of these points are plotted on the assembly board in their true position at the desired scale and a post immovably nailed there. With these posts fixed and all others free at the intersection of the slots, the entire template assembly expands or contracts to conform to the fixed ground-control points to establish a uniform scale.

When the entire area is covered by the templates the posts at the radial slot intersections represent the true positions of many points. These are pricked through the hole in the post to the compilation board underneath the template assembly, affording an intensive control pattern.

The slotted-template method affords excellent horizontal control for mosaics, planimetric maps, and small-scale contour maps. It is not quite accurate enough to control the setup of the plotting machine, which is usually controlled by a proper balance between ground control and aerial triangulation (bridging).

PHOTOGRAMMETRIC MAPS

Mosaics.—Mosaics have evolved from an uncontrolled and often misleading conglomerate assembly of pictures to a map of predictable accuracy and widely accepted usage. Most mosaics are compiled through the following steps:

1. Scattered ground control.
2. Nine points per picture, established by radial control (slotted template).
3. Comparison of the contact print with the control to determine what restitution is required.
4. Restitution, consisting of:

a. Enlargement or reduction of the picture as a whole, to compensate for altitude changes of the airplane and different elevations of the ground.

b. Tilt correction, to compensate for averticality of picture at the instant of exposure, and for average ground slope.

c. Fractional treatment: the breaking up of the picture into small parts to compensate for irregular ground.

d. Pyramiding (where the utmost in precision is required): roughly contouring the picture and making a series of ratio prints, one for each tier of elevation, all from the same negative. The pictures are then cut on these approximate contours, and reassembled, with the picture for each higher contour being pasted over the lower one. Thus, the error may be reduced to plus or minus half the interval of the pyramiding.

5. Stick-up and editing; *i.e.*, superimposing on the mosaic such items as grids, geographical lines and names, and marginal data.
6. Copying by quadrangles, on large plates or films.
7. Reproducing by quadrangles:

a. Photographically.

b. Lithographically, and so on.

Photo-Contour Maps.—A photo-contour map is quite similar to the pyramidal mosaic. It is made by projecting onto a single sheet of sensitized paper each photographic band between adjacent contours at its mean scale. A contour line is made to show between each pair of strips, yielding a very accurate photomap (mosaic) that also shows contours. Such maps are especially desirable for highway location. They are more expensive than topographic maps or ordinary mosaics.

Line Maps.—Line maps as distinguished from photographic maps may be planimetric or topographic. Planimetric maps delineate horizontal information as do topographic maps, which add contour lines. Both may show such features as roads, railroads, buildings, drainage, lakes, shorelines, swamps, and cadastral data including latitude and longitude, rectangular coordinates, political and geographical boundaries, property lines, and any special data, such as land classification, crop classification, and soil types.

Cadastral maps and other precise planimetric types are compiled by stereoplotting. Planimetric maps are often controlled on a slotted-template base. From this point on the methods of compilation depend on the character of the aerial photography and the preferences of the compiler. One method is by projecting from a contact print onto a base compiled by slotted template. The image is enlarged or reduced to conform to the control on the compilation board, and the detail is then traced. Some prefer, especially in country of steep relief, to establish radial intersections at intervals along all the principal features that are to be shown. These intersections guide a draftsman who fills in the features by hand.

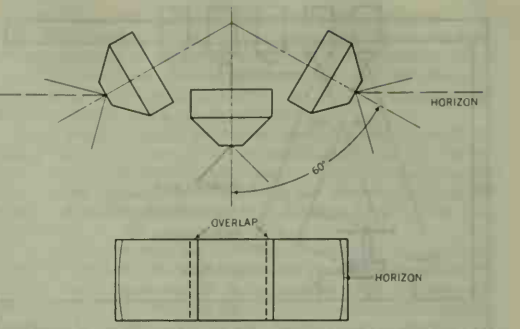

FIG. 4.—TRI-METROGON CAMERA ARRANGEMENT, SHOWING THE ONE VERTICAL AND THE TWO WING PICTURES

Planimetric maps are also compiled from oblique photography with such instruments as photo alidades in which a contact print or glass diapositive is observed in front of a transit, the centre of rotation of which is placed in the position occupied by the rear node of the taking lens. Attached below the vertical axis of this transit is a blade (similar to a conventional alidade) that plots the horizontal projection of the rays to the points sighted through the telescope. The true position of these points is determined by intersections developed by observing overlapping pictures.

Another extensively used device for placing planimetric detail from the photograph on the map is the sketchmaster, which is based on the camera lucida (*q.v.*). Through a half-silvered mirror or split prism the picture and the compilation sheet are seen simultaneously. After a good empirical registry is established between picture and compilation sheet, the detail is traced. Sketchmasters have been of three types; one plots from vertical pictures only, another draws maps from oblique pictures, while universal sketchmasters will draw from either type of photography.

Tri-Metrogon System.—The system derives its name from three K-17 cameras equipped with six-inch Metrogon lenses used as a unit. It was widely used in World War II, and since millions of square miles of Tri-Metrogon photography are in existence, the method is of interest, although it was substantially obsolete by the 1960s. The cameras are mounted with one axis vertical and the other two axes at 60° to the vertical and extending to the sides. Thus, the camera covers 7° or 8° above the horizon (fig. 4). This is important because the position of the horizon in the pictures is used to determine tilt. Since the horizon shows in each wing picture, two tilt determinations can be used as a check. If one or both wing pictures show a clean-cut water horizon or a horizon on fairly flat, low land, the tilt can be determined with good accuracy. If the terrain is mountainous, considerable estimating enters into the determination. Constants which should be known for satisfactory planimetric work are the focal length of each camera and the exact angular relationship among the three cameras.

In charting work the Tri-Metrogon photographs are assembled by slotted template. The template of the vertical picture is made in conventional manner. Probably the photo alidade is best for laying out oblique picture templates although such simplified apparatus as the rectoblique plotter and photoangulator were extensively used. The accuracy of the final result largely depends on the success in determining the tilt of the various pictures and the interlocking angles of the cameras. When the radial control plot has been completed the detail is put on the map with such devices as sketchmasters. Small-scale charts covering a large part of the world have been made this way.

Tri-Metrogon photography has also been used for topographic maps, but few existing plotting machines get effective production from it. The depth of focus of the multiplex is inadequate for the great range of the oblique photographs, and the excessive enlarge-

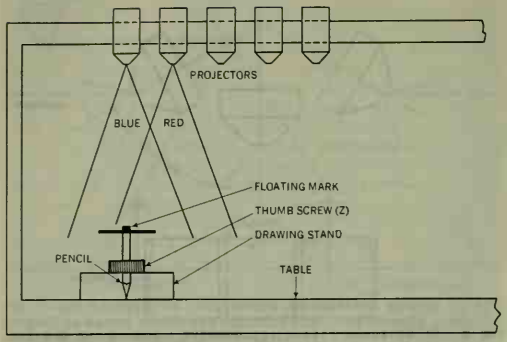

FIG. 5.—MULTIPLEX

The multiplex projects an overlapping pair or series of pictures in correct three-dimensional relationship. The images of complementary colours are viewed stereoscopically through spectacles with complementary coloured lenses. Drawing is accomplished by moving the drawing stand while keeping the floating mark in exact registry with the stereoscopic image

ment coupled with bad definition makes multiplex work fairly unsatisfactory. The stereoplanigraph has been best for mapping at scales for publishing at 1:25,000 from Tri-Metrogon photography. In this instrument the enlarging factor becomes so great and definition so poor beyond the centres of the wing pictures (25°± below the horizon) that accuracy is seriously impaired. The stereoplanigraph has, however, done the most effective job of contouring from Tri-Metrogon photography.

Tri-Metrogon equipment has been used at elevations up to 40,000 ft. The practical separation between flight strips is limited by atmospheric haze, topographical relief, and ground cover. It is generally usable to a total subtended angle of 110°; under favourable conditions to 135° or 140°. Practically, the principal point of the wing pictures is about the limit of successful coverage in terrain with considerable planimetric detail. Farther out than this such details as buildings and roads become very indistinct.

Wide-Angle Photography.—By 1960 the need to minimize flying and reduce photographic and control effort had moved interest away from Tri-Metrogon to the Wild system, composed of the RC9 camera (covering 120° with a single lens) and the A9 plotter. This camera of 9 × 9 in. format has a lens of 3.5-in. focal length; with it strips can be flown more than 12 mi. apart at 30,000 ft. altitude. One model will cover more than 80 sq.mi., and major clusters of horizontal and vertical control used with aerial triangulation may be held to one cluster of four points for each 500 sq.mi. Military aircraft at 50,000 ft. can fly strips more than 20 mi. apart with the RC9 camera, and a control cluster will satisfy about 1,300 sq.mi. or more. A good map could be plotted from this photography at a scale of 1:50,000 with 50-ft. contours.

Topography.—Topography is developed from aerial photography by two-dimensional and three-dimensional processes. All stereoscopic measuring uses a stereoscopic pair of pictures compared with a reference known as a floating mark. The floating mark may be placed at the intersection of the two projected rays of a common image as in the multiplex (fig. 5), or two marks may be fused just as the stereoscopic pictures are fused into one (fig. 6). When two marks are superimposed on the pictures and correspond exactly with conjugate images of any point, they appear to touch the ground at that point. If the eyes must converge more to see the mark than to see the image, the mark will appear closer to the observer (higher) than the image of the ground. If the eyes diverge to see the mark in relation to the image, the mark seems below the surface of the ground. In either system, this reference mark may be physically in contact with the pictures, or optically in contact with the image of the pictures in the more elaborate machines, and may be set for any desired ground elevation.

Parallax measurement applies very aptly to the two-dimensional processes. In principle, it also applies to the three-dimensional processes but not quite so obviously.

Two-Dimensional Processes.—The two-dimensional processes are simplest for deriving elevation data from a stereoscopic pair of aerial photographs. A pair of stereoscopic pictures is used in a stereoscope (*see* BINOCULAR INSTRUMENT) that has a pair of marks in contact with the pictures. The separation of the marks is set in accordance with the parallax of the desired elevation; the fused mark is moved along the exact ground surface of the stereoscopic image; and a contour is drawn. All points of the same elevation have the same parallax in vertical photography. The parallax is set once only for each contour. In drawing planimetry, a road that goes up- and downhill will require that the parallax be continuously changed. Maps drawn by the two-dimensional process emerge from the stereoscopic plotting instrument as conic projections (fig. 7). The map is a true conic projection only if the pictures of the stereoscopic pair were rectified (corrected for tilt) prior to their use. Stereocomparagraphs are the best-known type of equipment for this process. Acceptable maps can be made by the method even without rectified photographs if enough ground control is available. Unrectified pictures will give reasonably good results with one point of known elevation for approximately every two square inches of photograph. The same pictures, properly rectified, will give an excellent map with four known control points per stereoscopic model.

After the contours and planimetry have been traced off, the conic projection must be corrected. This means that each contour (which is at a different scale in accordance with the distance from the taking camera to the ground) and each planimetric detail (which is similarly displaced) must be proportionately corrected, elevation by elevation, to yield an orthographic map. This may be accomplished by tracing the detail off by pantograph (*see* LINKAGES), or similar device, changing the ratio for each change of contour; or it may be done in a projector by changing the projection ratio from contour to contour and tracing the orthographic map off on the projection screen.

Two-dimensional plotters go by such names as stereocomparagraph, contour finder, stereometer, and parallaxer.

Three-Dimensional Processes.—The three-dimensional process differs from the two-dimensional in that the light rays that originally formed the image are reprojected from the image in miniature back to the ground (its mechanical representation).

If the aerial camera were to remain in space in the same position in which the picture was taken and the film after development were replaced in the camera, the camera being used as a projector, each ray would return to the source from which it originated. Thus, if two cameras are retained in their spatial stereoscopic relationship, the conjugate rays from the two images of the common ground point when reprojected will fall back and intersect at that common ground point. Also if the cameras were moved to reduce their separation by half, the rays now would intersect at a distance halfway between the cameras and the ground. In other words, the scale of the entire system would be cut in half. If the cameras are only $\frac{1}{20,000}$ the distance at which they were separated in the air, a map can be drawn at precisely $\frac{1}{20,000}$ of the original scale.

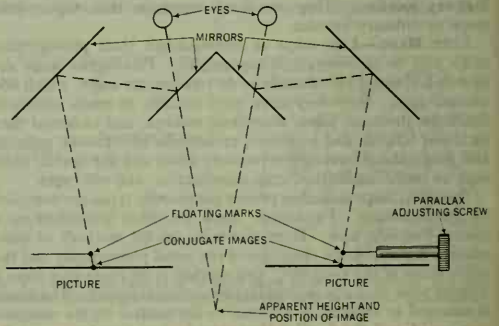

FIG. 6.—SIMPLE PARALLAX-MEASURING STEREOSCOPE

Similarly, the survey can produce a map at any desired scale.

The simplest example of the three-dimensional process is the multiplex. The original air pictures, which may have been 9×9 in., are reduced for multiplex use to $\frac{1}{4}$ original size. This permits use of very small projectors that can be brought close enough together to get the desired scale. Full-scale projectors using a 9×9 in. picture could not be placed close enough. For example, if a scale of 1:10,000 is desired, and the pictures were taken 3,000 ft. apart, the nodal points of the two projection lenses will be separated only $\frac{3,000}{10,000} = 0.3$ ft. or 3.6 in. Obviously, big projectors carrying 9×9 in. pictures could not be put this close together; the multiplex with its $2\frac{1}{4} \times 2\frac{1}{4}$ in. pictures can.

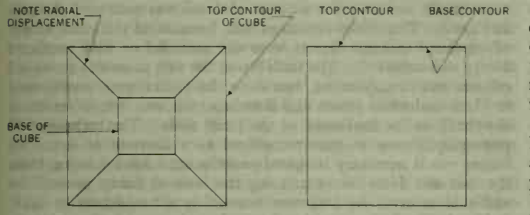

FIG. 7.—CORRECTION OF ORIGINAL PHOTOGRAPH. (LEFT) THE PHOTOGRAPH IS A CONIC PROJECTION. (RIGHT) THE MAP MUST BE ORTHOGRAPHIC. THIS CORRECTION IS MADE AUTOMATICALLY IN THREE-DIMENSIONAL PROCESSES, BUT IS AN ADDITIONAL OPERATION IN MOST TWO-DIMENSIONAL PROCESSES

The multiplex projectors have lenses of about 1.5-in. focal length, stopped down to a tiny aperture. Thus, at the focal plane of these lenses definition is sharp, and for a considerable distance on both sides of this plane the circle of confusion is small enough to be tolerable. In other words, the lenses have great depth of focus. This feature tends toward simplification of the multiplex system since the focus is sharp enough to draw a substantial band above and below the plane of most critical definition. Thus, without providing for any change of focus the multiplex operates effectively through a wide range of ground elevation.

Stereoscopic vision in the multiplex is by the anaglyph method: the two projectors (or, if more than two are used, alternate projectors) carry filters of complementary colours; *i.e.*, red and blue. The observer wears a red filter over one eye and a blue filter over the other to separate the two images and permit stereoscopic vision. The projected images are received on a drawing stand that can move over the compilation sheet, which is secured to a very flat table usually of slate or hand-scraped metal. The drawing stand carries a screen (parallel to the surface of the paper) that can be raised or lowered by a thumbscrew. In the middle of this screen a tiny point of light serves as the floating mark; directly beneath, a pencil draws on the compilation sheet as the stand is moved. In drawing contours the screen is set at the desired elevation, and the stand is then pushed around by hand. The operator observes the floating mark in relation to the plastic stereoscopic image and moves the stand so that the floating mark always follows the surface of the ground. In drawing planimetry, the floating mark is made to follow the feature; *e.g.*, a road. The operator works the thumbscrew of the screen, making it and the floating mark move up and down to follow the undulations of the feature.

Other three-dimensional processes use so-called universal equipment such as the Nistri, Poivilliers, Santoni, and Wild devices, and the Zeiss-aerotopograph. The word universal means that the machine will draw a map from vertical, oblique, and phototheodolite pictures.

All operate in a somewhat similar manner, except that the Porro principle is the basis of the Zeiss device. In the Porro system projection in the plotting machine is through a lens set at infinity focus and having identical optical characteristics with the lens of the aerial camera that took the pictures. Since projection through this lens is at infinity focus and the image on such a stereoplanigraph must focus in the plane of the floating mark, an automatic focusing lens is interposed between the projection lens and the floating mark. This is a telephoto lens that is constantly accommodating for the changing distance between the projection lens of the picture holder and the floating mark.

The Wild autograph has a ray rod passing through the mechanical representation of the nodal point. This rod actuates an optical system that scans the photograph in such a manner that the point viewed is always the point formed by a ray of light passing through the lens at the same angle as the ray rod.

These machines have a mechanical base by means of which the scale is set. In the case of the stereoplanigraph (fig. 8), the distance between the two floating marks is varied by changing this base, and on other types of machines the distance between the ground extremities of the ray rods is determined by the base adjustment.

The extensively used Kelsh plotter is similar to the multiplex except that it uses full-scale diapositives projected through lenses of focal length comparable to the air camera. This anaglyph system draws at about five times the scale of the original photographic negative. It compensates for lens distortion, although this is a minimal problem with modern air cameras.

In most three-dimensional plotters the picture holders (plateholders) are arranged so that they can be given X tilt and Y tilt around the nodal point. After the stereoscopic model has been perfected the two plateholders together can be made horizontal by the application of common X tilt and common Y tilt. The bases of these machines also carry BY and BZ adjustments. BY is an adjustment at right angles to the main base adjustment BX. BY is the equivalent of rotating the base in a horizontal plane. BZ is the adjustment for difference in the airplane elevation at the instant of exposure of the two pictures.

Stereoscopic pictures in a three-dimensional plotting machine can be put into perfect relative adjustment or correspondence without reference to the true horizontal. This is accomplished by a trial-and-error system that reveals imperfections of adjustment by vertical parallax. This is a splitting of the floating mark so that one mark appears above the other. When the adjustment is perfect no vertical parallax is present any place in the model. The subsequent process (known as horizontalizing) consists of moving the stereoscopic pair as a unit so that it bears the proper relationship to the base movements of the machine. Thus, before horizontalizing, the cameras (plateholders) will probably lie in some false inclined plane relative to the X and Y tracks of the base or the plotting table of the anaglyph plotters (Multiplex, Kelsh, etc.). The scale will also generally need adjusting. Horizontalizing is accomplished by measuring the distance between known ground control points and adjusting BX to get the proper scale, and by measuring the elevation of known points in the model and adjusting common X tilt and common Y tilt.

Drawing is accomplished by turning handwheels that actuate the X and Y movements and a footwheel controlling Z. The X and Y motion of the handwheels is transferred to a pencil on a plotting table. This table is connected to the stereoscopic machine through a gear box so that different ratios may be established between the two. It is not unusual to draw the map on the plotting table at six times the picture scale; frequently the scale is en-

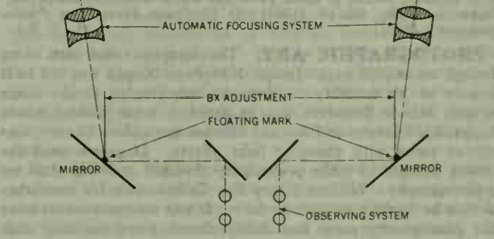

FIG. 8.—ELEMENTS OF STEREOPLANIGRAPH

larged as much as ten times horizontally.

This is related to a major criterion used in planning a stereoscopic survey. There is little relationship in most stereoscopic systems between the horizontal scale and flight altitude, because the horizontal scale can be enlarged or reduced. The determining factor of the flight altitude is the accuracy required of the contours. Thus the best plotting machines permit flying at 2,500 or more times the permissible contour tolerance. From this elevation a map can be drawn in which at least 90% of all points tested will check out within ½ the contour interval.

The wide choice of plotting scales gives universal plotting equipment an advantage over the multiplex when the plotting scale is restricted by the depth of focus of the projectors. One of the principal differences between these plotting machines is that, with the multiplex, drawing is accomplished by pushing the stand around over the compilation sheet, the elevation being changed by a thumbscrew. On the universal machine, drawing is accomplished by turning handwheels, the left hand controlling the X motion of the machine, and the right hand controlling the Y motion. On such universal machines the elevation of the floating mark is controlled by a footwheel. Thus, when contours are drawn, the footwheel sets the proper elevation. At this setting the floating mark, like that of the multiplex, is restrained to move in a given horizontal plane. For drawing planimetry with the universal machine, the operator looking through the stereoscope makes the handwheels follow the ground feature and with the footwheel keeps the floating mark moving up and down to conform with the elevation of the ground surface.

By the 1960s an extensive demand had developed for large-scale cross sections fed by stereoplotters into electronic computers and tabulators. Instead of drawing a map the plotter reads elevations at intervals along a cross section. These and readings of distance on either side of the centre line are fed to a tabulating typewriter and punched on a computer card. The process is extensively used for computing quantities of earth in highway design.

Summary.—Aerial photography and photogrammetry augment but in no way eliminate ground surveying. In all photogrammetry some, and often considerable, ground surveying is required for control. Many areas to be mapped are too small to justify the cost of flying to them or are too remote to absorb this cost. Areas obscured by vegetation will probably continue to be mapped with the traditional plane table.

It is not possible to drive a stake in the ground from an airplane; and the construction project must be laid out by conventional survey processes. Aerial photography greatly enriches visual information available about the surface of the ground. It frequently provides a more complete visual inventory more rapidly and cheaply than could be obtained any other way.

Photogrammetry usually minimizes the more costly phases of conventional ground surveys. Which will be more practical depends on such factors as purpose of the survey, scale of map, contour interval, size of area, distance from operating base, character of ground cover, data to be shown on the map, and character of the terrain. A study of the individual project will determine whether the survey should be by photogrammetric methods, by conventional ground methods, or by a combination of both. *See* also SURVEYING; MAP.

PHOTOGRAPHIC ART. Photography came into being through an artistic urge: Joseph Nicéphore Niepce was led to it because of his inability to draw on lithographic stone; Louis Jacques Mandé Daguerre was an artist, a scene painter whose illusionistic Diorama in Paris and London was a show of enormous painted views with changing light effects. Daguerre used the camera obscura to make preliminary sketches and was thus led to photography. William Henry Fox Talbot made his researches because he found it difficult to draw. It was not mere coincidence that photography came into being almost simultaneously with means of multiplying pictures in great quantities (lithography) and with semimechanical means of picturemaking (the silhouette and the physionotrace). The underlying chemical and optical principles had long been known, but the idea of using the light-sensitive property of silver salts to record the optical image of the camera did not occur until there was a demand for pictures following the rise of the *bourgeoisie* after the French Revolution.

The first criticism of photography was necessarily based on a comparison of it with painting or drawing, since no other standards of picturemaking existed. The Parisian painter Hippolyte (Paul) Delaroche, when questioned about the value of the daguerreotype to artists, went so far as to say that the "process completely satisfies art's every need." Photography's remarkable ability to record a seemingly inexhaustible amount of detail was marveled at again and again. The critics regretted that, because of the great length of exposure, moving objects were not recorded or were rendered blurry and indistinct. The inability of the first processes to record colours was disappointing, but since the critics were conditioned to black-and-white prints and drawings, this was not so serious a drawback as the harshness of the tonal scale. The technique of photography was at once recognized as a shortcut to art. No longer was it necessary to spend years in art school drawing from the cast and from life, mastering the laws of linear perspective and chiaroscuro. As Daguerre boasted in a broadsheet in 1838, "with this technique, without any knowledge of chemistry or physics, one will be able to make in a few minutes the most detailed views. . . ." But formal art education had a purpose over and above the mastery of technique. The discipline taught the student to observe, and it gave him a feeling for the significant moments of time and an intuitive sense of composition. Already Leonardo da Vinci in his "treatise on painting" had warned against the use of the camera obscura as a shortcut to picturemaking, because it often led to superficial results, lacking in the qualities that distinguish a work of art from an illustration.

D. O. Hill and R. Adamson.—In the hands of artists, photography quickly showed its artistic possibilities. David Octavius Hill, a Scottish landscape painter, became interested in Talbot's calotype process. In 1843 he decided to paint a group portrait of the Church of Scotland ministers who in that year resigned their benefices and formed the Free Church of Scotland. There were 474 figures to be painted, and in order to simplify this enormous task, Hill turned to photography. He enlisted the aid of Robert Adamson, an Edinburgh photographer, and together they made hundreds of portraits. They did not confine themselves to the members of the church meeting, but included people from all walks of life. In view of the fact that they posed their sitters out-of-doors, in strong sunlight and with exposures of about one minute, it is hard to understand how Hill and Adamson managed to retain that spontaneity which is so essential to the success of a photographic portrait. They photographed the fishermen and their wives at Newhaven, Scot., posing them in groups reminiscent of paintings, and some of their landscape photographs show a startling affinity to watercolour drawings. The work of Hill and Adamson was forgotten after the 1860s but was revived in the early 1890s when J. Craig Annan made modern prints from the original paper negatives.

Daguerreotypes in the U.S.—By universal consent, the United States led the world in the production of daguerreotypes. It has been claimed that the first portraits made by photography were produced in the United States. By the late 1840s photography was a big business. Every city of size had its "daguerrean artist," and ingenuity led to the use of machinery and production line processing and though the work of the Boston, Mass., firm of Albert Sands Southworth and Josiah J. Hawes cannot claim to rival the artistic quality of Hill and Adamson, these two daguerreotypists had a fine perception of the individual. Instead of the stereotyped lighting and posing formulas of the average daguerreotypist, they showed the greatest variety, and they did not hesitate to present their sitters unprettified and "as they were." Lemuel Shaw stands with crumpled coat and unruly locks of hair under a glare of sunshine; John Quincy Adams sits in his living room; Lola Montez lolls over the back of a chair.

Formulation of an Aesthetic Theory.—In England the hey-

day of photography followed Frederick Scott Archer's invention of the wet collodion process in 1851. This new technique rapidly displaced and made obsolete the daguerreotype and calotype. Professionals had found the need of banding together; and the new process, which was free from all patent restriction, attracted countless amateurs. Rallying points sprang up: in 1853 the Photographic Society (renamed, in 1897, the Royal Photographic Society) was formed in London; and in the next year the Société Française de Photographie was founded in Paris.

Up to that time there had been little conscious effort to impose artistic rules on the production of photographs. No particular distinction seems to have been made between photographs produced for an aesthetic intent and those made for documentary purposes. An exhibition of photographs, including examples of the work of Hill and Adamson, was shown at the Crystal Palace in London, 1851, in the section "Philosophical Instruments." In the preceding year Gustave le Gray, a French professional, had sent eight photographs to a competitive art exhibition in Paris. They were accepted by the jury and catalogued as lithographs. When it became known that they were photographs, they were withdrawn by the organizing committee.

Photographic societies undertook to remedy this situation and began to examine the position of artistic photography in relation to scientific photography. At the first meeting of the Photographic Society the president, Sir Charles Eastlake, who was at the same time president of the Royal Academy, invited Sir William Newton, a miniature painter by profession, to read a paper "Upon Photography in an Artistic View" (*Journal of the Photographic Society*, i, 1853). His argument was that, to be useful to the painter, photography should depict natural objects "in accordance (as far as it is possible) with the acknowledged principles of Fine Art." One way in which the photographer could make his results "more like works of art," Sir William pointed out, was to throw the subject slightly out of focus. The extreme blue-sensitivity of wet collodion plates rendered the sky areas so dense that they appeared as blank paper on the print. To overcome this failure of the photographic process he recommended liberal retouching and free use of handwork on the negative.

Combination Printing.—An outcome of the urge to create photographs which would fit a priori concepts of art was the technique of making one print from several different negatives. The most famous example was made by O. G. Rejlander, a Swedish painter, who had received an art education in Rome and was practising photography in England. It was a painterly composition, 31 × 16 in. in size, printed from no fewer than 30 separate negatives. The picture was entitled "The Two Ways of Life," and showed, in allegory as obvious as it was sentimental, that the way of the blessed led through good works and the way of the damned through vice. Rejlander, who described the technique in photographic journals, stated that his purpose was to prove to artists the artistic possibilities of photography, which they had denied. The photograph was shown in the Manchester Art Treasures Exhibition of 1857 and was purchased by Queen Victoria for Prince Albert.

H. P. Robinson.—This technique stimulated Henry Peach Robinson, a professional photographer who had studied art as a young man. He became famous with a five-negative combination print, "Fading Away," in 1858. The subject depicted a dying girl, and this was considered by critics as too painful a subject to be represented by art. Perhaps the implied authenticity of photography bothered them, because painters had long presented subjects of far more painful nature. Robinson became a most articulate member of the Photographic Society, and his teaching was even more influential than his photography. In 1869 appeared the first of many editions and translations of his book, *Pictorial Effect in Photography*. Robinson went a step further than Newton; he offered photographers a set of rules. From a then outmoded handbook on painting, he borrowed compositional formulas the use of which, he claimed, would bring artistic success. The student was instructed to arrange his models in pyramidal compositions, and examples from the work of Sir David Wilkie, a popular painter of genre scenes, were given to show how this artist used the triangular form of composition. The importance of balance was stressed, and the opposition of light against dark was made clear. The fault of the book lay not only in the assumption that rules set up for one art form can be applied to another, but also in its intellectual and academic approach to art.

Robinson's work is, by modern standards of taste, weak and artificial. Not only did he practise photomontage, but he preferred to work in the studio, against painted backdrops and with props of natural objects, even foliage, mounted on casters. When he did photograph in the country, he took models with him, dressing them up to play the part of country girls, instead of turning to the genuine thing.

J. M. Cameron.—Using a lens of 30-in. focal length requiring exposure of several minutes and a definition rapidly falling off from the centre, Julia Margaret Cameron produced a remarkable series of portraits between 1864 and 1874. The success of these portraits, representing friends prominent in literary and artistic circles, cannot be laid to technique, however, because her genre studies, too obviously based on Pre-Raphaelite paintings, were weak and sentimental. The key to the success of the portraits lies in their artistic intensity. "When I had these men before my camera," she related in her "Annals of My Glass-house" (*Photographic Journal*, lxvii, pp. 296–301, 1927), "my whole soul has endeavoured to do its duty toward them in recording faithfully the greatness of the inner man as well as the features of the outer man. The photograph thus obtained has been almost the embodiment of a prayer."

Adam-Salomon and Retouching.—While the Parisian caricaturists and portrait photographers Nadar and E. Carjat produced great portraits in a simple and straightforward technique reminiscent of early daguerreotypists, the sculptor A. S. Adam-Salomon introduced a false note into photographic portraiture by retouching. Arguments were frequent in the 1860s over the legitimacy of retouching, particularly of portraits. Some prints of Salomon's were tested by the Edinburgh Photographic Society in 1868 to ascertain "whether they were pure photographs or indebted to retouching for their beauty." It was found that they were retouched.

O. W. Holmes on Photography.—There was one form of photography in which retouching or any other form of handwork was virtually excluded, and that was stereographic work. The paired images which, when viewed properly, produce the most astonishing illusion of three dimension, depend upon the most minute and exact differences in detail to render their startling effect, and this precision cannot be imitated satisfactorily by hand. Love of stereographs led the U.S. physician and writer Oliver Wendell Holmes to write three articles in the *Atlantic Monthly* in which he put down the basis of a functional aesthetic which was almost diametrically opposed to what Newton had recommended in London. To Holmes the photograph had characteristics which no other art could rival. Far from regretting that the camera had not been used in accordance with the accepted rules of art, Holmes praised what appeared to some the defects of the process. "The very things which an artist would leave out, or render imperfectly, the photograph takes infinite care with, and so renders its illusions perfect. What is the picture of a drum without the marks on its head where the beating of the sticks has darkened the parchment?" (*Atlantic Monthly*, iii, p. 746, 1859.) "In a perfect photograph," he added, "there will be as many beauties lurking, unobserved, as there are flowers that blush unseen in forests and meadows." Holmes was but one voice against the many. The aesthetic value of straight photography was not generally recognized, and the work of those who recorded the battlefields of the Crimean War and the American Civil War and who traveled throughout the world was overlooked by the aestheticians.

Naturalistic Photography.—The introduction of factory-produced dry plates in the 1880s attracted an increasing number of amateurs to photography. In comparison with the messy and awkward wet plates, the dry emulsions were revolutionary. The photographer could buy ready-made plates and process them at

his convenience. Small hand cameras freed him of his tripod, just as the dry plate had freed him of the necessity for taking a dark tent on his travels.

Peter Henry Emerson felt the artificiality of the Robinson school, and he set against the latter's theories another viewpoint which he named naturalism, and which he described in his *Naturalistic Photography,* first published in 1889. He believed that photography was potentially a great creative art, and that it did not need to be bound down to rules set up for painting. "Naturalism," he wrote, "is an impersonal method of expression, a more or less correct reflection of nature wherein (1) truth of sentiment, (2) illusion of truth of appearance (so far as is possible) and (3) decoration are of first and supreme importance."

Emerson sought a scientific basis for pictorial photography. He analyzed the physiology of vision in order to find out how the camera can simulate human perception. He reasoned that since the eye sees distinctly only a small part of what lies before it, while the surrounding area appears indistinct, it should be possible to reproduce this phenomenon by control of focusing. Only a small part of the photograph should be sharp; the rest should be just slightly out of focus. Today we recognize that this theory of vision is fallacious, because the eye, unlike the lens of a camera, is a living organism, which scans the field of view constantly so that the mind receives a composite report and the impression of full detail. The naturalistic theory was an advance over Newton's, for Emerson believed that the photographer should rely entirely on controls which were themselves part of the photographic process. In addition to control through differential focusing, he advised the careful use of developing and printing methods.

Emerson took a large number of photographs of the amphibious life of the simple country folk on the Norfolk Broads, which were far removed from the artificial genre studies of Robinson and very close to the graphic work of J. F. Millet which Emerson greatly admired. Imbued with a deep artistic feeling, Emerson's photographs fired a number of other amateurs to seek inspiration in nature as the first generation of photographers had done. He published his photographs in limited editions in handsome folio volumes as original platinum prints or as photogravures and photoetchings.

The scientific findings of Hurter and Driffield led Emerson in 1891 to renounce the art claims he had made for photography. A great artist, he said, had shown him that the mere reproduction or translation of nature was not art. The fallacy of this argument lay, of course, in the definition of art. It appears that "art" and "painting" were almost synonymous to Emerson when he wrote his retraction. What really happened was that Emerson's preaching on differential focusing led to the use of soft focusing lenses and other blurring effects such as the use of very coarse paper. Emerson dramatically announced his views in a black-bordered pamphlet "The Death of Naturalistic Photography."

The Linked Ring.—In his book Emerson had a good deal to say about photographic exhibitions. He felt that they were poorly organized. He recommended that photographs be framed in simple white moulding and that they be exhibited on one line in galleries, not plastered over the wall with the frames practically touching. He rightly felt that pictorial photographs should be isolated, instead of being lumped together with work done for scientific, technical, and other nonaesthetic purposes.

Dissatisfaction with the scientific bias of the Photographic Society under the presidency of Sir William Abney caused a split in the society in 1892. A group of pictorially minded members, under the leadership of H. P. Robinson and George Davison, formed a society for the exclusive purpose of furthering "the development of the highest form of art of which photography is capable." (*Camera Notes,* p. 119, the Camera Club of New York, 1901.) The society was named the Linked Ring. They held annual exhibitions which they referred to as *salons,* a name borrowed from the painting world, and which demonstrated their artistic motivation. By 1901 it was their proud boast that "through the *Salon* the Linked Ring has clearly demonstrated that pictorial photography is able to stand alone and that it has a future quite apart from that which is purely mechanical." (*Camera Notes,* p. 119, the Camera Club of New York, 1901.)

Stieglitz and the U.S. School.—In 1887 Emerson, judging a competition for the *Amateur Photographer,* had awarded a prize to Alfred Stieglitz, a young American who was studying in Germany. It was the first award which Stieglitz had received; the first recognition of one who was to carry pictorial photography to a high level, not only with his own work, but in his constant championship of all that has been progressive in photography and other forms of modern art.

When Stieglitz returned to the U.S. he found that photography was a passing craze, and that the New York Society of Amateur Photographers threatened to change their organization into a bicycling club. After serving as editor of the *American Amateur Photographer* for a number of years he organized a sympathetic group in the Camera Club, New York City, and founded a handsome periodical, *Camera Notes,* which, devoted exclusively to pictorial photography, was outstanding for the unusually high quality of its illustrations. Stieglitz was one of the first to demonstrate the pictorial possibilities of the hand camera with his straightforward photographs of New York under all weather conditions.

In 1900 F. Holland Day brought to England a collection of the work of the new photographers who had emerged largely because of the guidance and the example of Stieglitz. The showing, although not fully representative, included the work of A. L. Coburn, Frank Eugene, Gertrud Käsebier, Edward Steichen, and Clarence White. It was characterized by an emphasis upon aesthetic intent, by a variety of printing techniques, and by subtle presentation. Day, addressing the Royal Photographic Society, where the exhibition was held, referred to the exhibitors as the new school which "holds tenaciously that photography may be, if it is not yet, a fine art." (F. Holland Day, *Photographic Journal,* Royal Photographic Society, October 1900.)

The Photo-Secession.—Stieglitz and his friends, disturbed by the lack of standards and the general conduct of photographic exhibitions in the U.S., formed in 1902 the Photo-Secession. They chose the word "secession" to show their split with the *status quo,* just as the German and Austrian painters had used the same word to make manifest their independence of officialdom. The record of the Photo-Secession is contained in the 50 issues of *Camera Work* which were published by Stieglitz between 1903 and 1917. The society had a gallery, known as "291" from the street number of Fifth Avenue, New York City, where it was located, and there Stieglitz showed not only pictorial photographs, from Europe and the U.S., but also (in later years increasingly more than photographs) European *avant-garde* art selected by Steichen in Paris. *Camera Work* contains reviews of these exhibitions, photogravures, and other reproductions of the highest quality, and stimulating essays.

The Photo-Secessionists were much concerned over the recognition of photography as a fine art. The independence of pictorial photography had been proved, but as yet little interest had been shown officially by art museums. In 1910 the group organized an exhibition of about 500 prints by leading pictorial photographers from all over the world in the Albright Art Gallery, Buffalo, N.Y. The show created a sensation. Some of the exhibited prints were purchased by the gallery; for the first time in the U.S., photographs were admitted to an art museum on an equal footing with paintings and drawings as they had been at the Manchester Art Treasures Exhibition in England in 1857, and by Alfred Lichtwark, director of the Hamburg Kunsthalle from 1893 to 1903.

Transition.—The last issues of *Camera Work* contained photographs by Paul Strand which showed a new approach. There were views looking down from unusual angles; there were bowls in quasi-abstract arrangement; there were striking unposed open-air portraits of a type which 20 years later were to be called candid. One of the first Photo-Secessionists, A. L. Coburn, made a series of photographs looking down from a tall building, which he published as *New York from Its Pinnacles,* noteworthy for the way in which emphasis was thrown on form. He also made the first completely abstract photographs called Vortographs, which he contributed to *Photograms of the Year* in 1917.

There was other evidence that new trends were coming to the surface at the close of World War I. Edward Steichen renounced both his painting and his Impressionistic photography, which had been characterized by broad, simple effects, often rendered by gum prints, a process which was readily adaptable to manipulation. He turned to a precise, clean-cut way of working, which he applied to illustration work. The painter Charles Sheeler used the camera to record the stark beauty of Pennsylvania barns and the forms of industrial structures. Edward Weston in 1925 gave up the soft focus, often sentimental landscapes, and figure pieces which had brought him fame and discovered the beauty of close-up details and isolated form, which he recorded in full detail and with brilliant contrasts. Alfred Stieglitz carried his work further; in 1924 he began the "Equivalents" series in which the ability of the camera to record nature gives way to its use as a creative instrument, capable of imparting the most intense emotional reactions. He found in the photographic series a powerful means of expression. A portrait, for example, consisted of many separate yet mutually related photographs.

Influence of Abstract Art.—In Germany, a similar revaluation of the photographic medium had taken place in the mid-1920s, largely under the influence of Albert Renger-Patzsch, pioneer of the NeueSachlichkeit (New Objectivity) movement in photography which ran parallel to similar intentions of realistic, objective representation in painting and the cinema (*Potemkin, The Joyless Street*). Under W. Gropius' leadership, much of the modern idiom of architecture and industrial design originated at the Bauhaus, the famous experimental art school, where from 1923 to 1928 L. Moholy-Nagy, an abstract painter, directed a class of experimental photography in order to find out what the other art and craft subjects could learn from photography and to extend the boundaries of photographic image making. They discovered that there was a photographic vision which in itself was aesthetically stimulating. Instead of deploring the distortions caused by the use of lenses of abnormally short or long focal length, they delighted in the new forms thus created. They tipped the camera up and pointed it down. Christian Schad in 1918, Man Ray and Moholy-Nagy at later dates made highly complex abstract compositions by placing objects directly on sensitized paper, which was then exposed to light. The objects not only left negative images of their profiles, but also, if they were translucent, gradations of light modulated by them. Aesthetically, these "photograms" or "rayographs" were the photographic equivalents of abstract paintings of the period; technically, they were revivals of Talbot's photogenic drawing process.

Contemporary Photographic Art.—The experimental work of the 1920s served to break down the barriers of conservatism and to reveal that photography is an artistic medium with its own special characteristics. After 1930, three closely related trends became increasingly important: (1) a return to the use of large cameras and large negatives from which are made contact prints, rich in detail and brilliant in tonal gradations, that interpret in the most vivid way the subject before the camera; (2) the exploitation to the utmost of new technological developments in lenses, films, and lighting equipment to capture the fleeting moment and to photograph things and places never before recorded upon film; and (3) the shaping of photography to metamorphize subject matter so that all sense of reality is seemingly lost in an abstract form which, it is claimed, has an independent aesthetic existence.

Apart from Albert Renger-Patzsch, the German pioneer of "New Objectivity," the masters of the first group are largely American: Alfred Stieglitz (d. 1946), Edward Weston (d. 1958), Paul Strand, and Ansel Adams. Their work is distinguished by an impeccable classic technique and a deep respect for subject. They prefer in general to photograph by natural light, and have found their richest subject matter in the natural scene, architecture, and out-of-door portraiture. Their attitude toward the final photograph is comparable to that of an etcher to his print. The photograph is an entity, to be mounted with the greatest of care upon a white card, and to be preserved and respected as a work of art.

The second group has found one of its greatest exponents in Henri Cartier-Bresson. This French photographer found that the powerful lenses which can be used with miniature camera and high-speed film gave him an opportunity to photograph "on the run" and to find compositions which exist for a brief interval of time. To him the camera is "an extension of the eye," and his photographs—mostly of people—are characterized by their immediacy and by their unusual form.

Advances in lighting equipment, especially the development of the electric flash and the yet more powerful electronic flash, gave the photographer an extension of the medium. Steichen pioneered in the use of theatrical lighting in his portraits of celebrities; Barbara Morgan captured the essence of the dance in her remarkable action photographs. Reportage photographers consider themselves primarily journalists with a camera and many have pushed their work beyond that of topical records. These photographers intend their photographs to be presented upon the printed page. They seldom are interested in the single, mounted print as an aesthetic unit. (*See* also PHOTOJOURNALISM.)

More recently, some photographers in almost every country have used photography in a seemingly abstract manner. But where the abstractionists of the 1920s were, like the Cubist painters, content to present their work as nonrepresentational and of value for its challenging and stimulating form and colour, the new nonrepresentational photographers challenge us to find hidden meanings in their photographs. Deliberately choosing unlikely subject matter—peeling paint, crumbling walls, rock formations—they invite us to overcome subject association in the discovery through their images of forms never before perceived. In Germany a short-lived movement led by Otto Steinert proposed the founding of a school of "Subjective Photography," based somewhat obviously on the pre-World War II work of the Bauhaus. In the U.S., the chief exponent of the theory of "Equivalents" is Minor White, through his sensitive photographs, his teachings and his editing of the quarterly *Aperture*. The bold vision of Aaron Siskind and others has brought to its highest point the metamorphosis of insignificant detail to a seemingly abstract image which, to the perceptive, is yet rooted in reality.

There have also been remarkable developments in the use of books and exhibitions as vehicles for photographic art. The exhibition "The Family of Man" (1955), organized by Edward Steichen for the Museum of Modern Art, New York, used photographs in a spectacular way to convey a theme of universal appeal. The United States Information Agency, to inaugurate the Congresshalle in Berlin (1957), held an exhibition, "A Nation of Nations," of work by leading American photographers, selected by Nancy Newhall.

Collections of Art Photography.—There exist extensive collections of equipment and photographs as specimens of processes in a number of official technical and scientific institutions. Foremost among them are: the Science Museum, London; the Kodak Museum, Harrow, England; the Smithsonian Institution, Washington, D.C.; the Musée du Conservatoire National des Arts et Métiers, Paris; the Musée de l'Histoire des Sciences, Brussels; and the National Technical Museum, Prague. The building of collections of artistic photographs, however, has been slow in comparison with the collecting of other forms of art, and up to the 1960s very few art museums have taken an interest in the subject.

The most complete collections showing the development of the art of photography in many countries from its origin to the present day are those at George Eastman House, Rochester, N.Y., and the Gernsheim Collection, London. Both the Royal Photographic Society in London and the Société Française de Photographie in Paris possess notable material relating chiefly to the period before World War I, but since these collections rely entirely on gifts, they are rather sporadic and largely on a national basis. The Metropolitan Museum of Art, New York, also relying mainly on gifts, has a small and representative collection, chiefly relating to the period before 1914, whereas the Museum of Modern Art, New York, which formed an active department of photography in 1940, is particularly strong in contemporary work. The print departments at the Library of Congress and at the Bibliothèque Nationale in Paris have very large though haphazard collections

acquired originally through their function as national depositories of copyright material. The Library of Congress has the most extensive collection of photographs of the American scene, including Civil War photographs, and all the negatives taken for the Farm Security Administration. A beginning was made in 1947 to sift and catalogue the material which had been neglected for generations, and it is hoped that through a similar reorganization and cataloguing at the Bibliothèque Nationale both these great storehouses of photographs will eventually become readily available to the public.

Some other art museums have small collections of either old or contemporary photography, for example, the Victoria and Albert Museum, London, the Art Institute of Chicago, and the Staatliche Landesbildstelle, Hamburg, Ger. Several European museums, stimulated by exhibitions arranged from the Gernsheim Collection on the aesthetic development of photography, are in the process of building up collections; *e.g.*, the Museum of Modern Art in Stockholm, Sweden; the Stedelijk Museum, Amsterdam, the print department at the University of Leyden, Netherlands; the Folkwang Museum, Essen, and the City Museum, Munich, Ger.

TECHNIQUES OF PHOTOGRAPHIC ART

Anyone who has mastered a few simple instructions can make printable negatives with a pocket camera. Because it is impossible for the untrained beginner to achieve such acceptable results in any other medium, photography has sometimes been called the easy art. But to bridge the gulf between the taking of such casual snapshots and the production of photographs that can be classed as art is certainly no easy task. To the mastering of his tools and the perfecting of his technique, the photographer must devote just as much time and effort as does the musician or the painter. Since the nature of the photographic process determines the artist's approach, we must have some knowledge of the inherent characteristics of the medium in order to understand what constitutes the aesthetic basis of photographic art.

Photography must always deal with things—it can not record abstract ideas—but far from being restricted to copying nature, as many suppose, the photographer has ample facilities for presenting his subject in any manner he chooses. First, an infinite number of compositions can be achieved with a single stationary subject by varying the position of the camera, the camera angle, or the focal length of the lens. Second, any or all values can be altered by change of light on the subject, or the use of a colour filter. Third, the registering of relative values in the negative can be controlled by length of exposure, kind of emulsion used, and method of developing. And finally, the relative values in the negative can be further modified by allowing more or less light to affect certain parts of the image in printing. The photographer is restricted to representing objects of the real world, but in the manner of portraying those objects he has vast discretionary powers; he can depart from literal recording to whatever extent he chooses without resorting to any method of control that is not of a photographic (*i.e.*, optical or chemical) nature.

But the artist's use of these controlling powers must be conditioned by two factors: (1) the nature of his recording process, and (2) the nature of his image. There is a frequent cause of mistaken understanding in the belief that the camera's image reproduces nature as the human eye sees it. On the contrary, its ability to record things as the unaided human eye can never see them is one of the most important attributes of photography. The human eye can focus on but one small area at a time; consequently, we observe an object or a scene only by letting our eyes rove over it in a series of short jumps. The assortment of images thus recorded are flashed to the brain which sorts and edits them, automatically discarding some as of no importance and emphasizing others, according to its individual conditioning. The impersonal camera eye makes no such distinctions; every detail within its field of vision can be recorded instantly and with great clarity. In the time the eye takes to report an impression of houses and a street the camera can record them completely, from their structure, spacing, and relative sizes, to the grain of the wood, the mortar between the bricks, the dents in the pavement. The image that is thus registered has certain characteristics that at once distinguish it from the products of all other graphic processes. In its ability to register fine detail and in its ability to render an unbroken sequence of infinitely subtle gradations, the photograph cannot be equaled by any work of the human hand. For this reason any manual interference with the image at once destroys those very qualities that give the true photograph value as an art form. From these two facts we may draw an obvious deduction: if the recording process is instantaneous and the nature of the image such that it cannot survive corrective handwork, then it is clear that the artist must be able to visualize his final result in advance. His finished print must be created in full before he makes his exposure, and the controlling powers enumerated above must be used, not as correctives, but as predetermined means of carrying out that original visualization. As in the mastery of any other graphic form, years of experience are necessary in photography before technical considerations can be made entirely subordinate to artistic aims. The ability to prevision the finished print is the photographer's most important qualification and in order to attain it he must concentrate on learning to see in terms of his tools and processes. Having chosen the simplest possible equipment (so as not to complicate his task needlessly) he first learns by experiment the potentialities and limitations of each instrument and process. He must learn the field of his lens, the tone scale of his film and paper emulsions; he must learn to judge the strength and quality of light; he must learn to translate colours into their relative monochrome values and know how those values are affected by the use of different filters.

He must learn the kind of negative necessary to produce a given kind of print, and then learn what kind of exposure and development will produce that negative; then, having learned how those needs are fulfilled for one kind of print, he must discover how to vary the process to get other kinds of prints. Gradually, with experience, this knowledge becomes intuitive; the photographer sees a scene or object in terms of his finished print without having to think of these processes any more than a musician playing a piece thinks of the whereabouts of the next note he will sound or how much pressure he will use in sounding it.

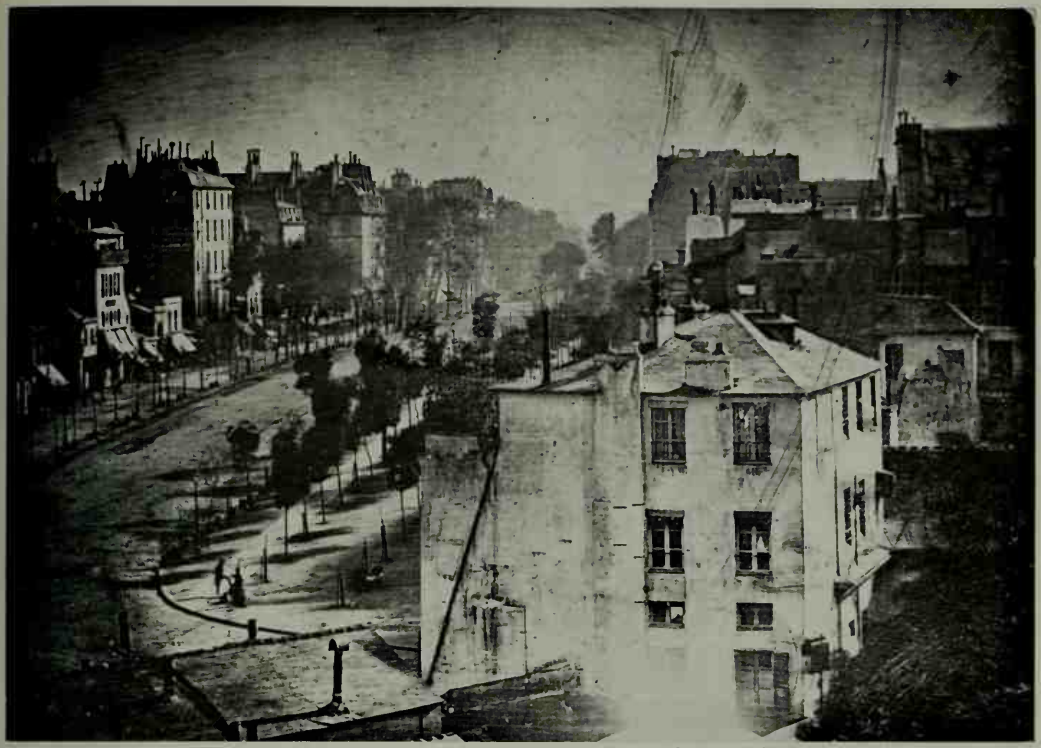
The Print.—The value of the photograph as a work of art depends primarily on the photographer's seeing before exposure, but its artistic value can be determined only by an examination of the finished print.

Exposure records the photographer's seeing; developing and printing execute it; so no matter how fine the original vision, if it has not been faithfully carried out in subsequent procedures, the resulting print will suffer. The clarity of image and delicacy of gradation that characterize a fine photograph demand a special kind of surface for their best presentation. A rough surface destroys the integrity of the image; a smooth surface retains it. A shiny or reflecting surface enhances the beauty of image quality, while a dull or absorbing surface tends to obscure it.

For beautiful image quality, the best of the old daguerreotypes can hardly be matched. The positives were made directly on the metal base and the small pictures were esteemed for their exquisite rendering of fine detail. The photo-painters, who did away with all things characteristically photographic, often used papers of independently beautiful surface texture for their prints. The result of such a combination is that the paper competes with the image instead of becoming a part of it.

Among modern processes the nearest approach to the fine image quality of daguerreotypes is a glossy print. Unfortunately, glossy paper is still held in general disfavour among creative photographers. It is said to be harsh and cold and only suitable for commercial work.

These erroneous beliefs are partly a hangover from the heyday of photo-painting and partly a result of the difficulty of making good glossy prints. The glossy surface reveals the image with such clarity that minor blunders, which might escape detection on the more veiled, dull-surface papers, are at once exposed. However, the glossy surface has the advantage of a longer scale which makes it possible to reproduce more of the negative and allows



COLLECTION OF THE BAVARIAN NATIONAL MUSEUM, MUNICH

"Paris Boulevard," daguerreotype by Louis J. M. Daguerre, 1839. On the corner at lower left is visible the first human form ever photographed. Though blurred, it is a man having his boots brushed. The street appears empty because the early daguerreotype process was so slow that only stationary objects could be captured on the plate

GEORGE EASTMAN HOUSE

"Chief Justice Lemuel Shaw," daguerreotype by A. S. Southworth and J. J. Hawes, 1851. An early portrait of an eminent Massachusetts jurist

PHOTOGRAPHIC ART

GEORGE EASTMAN HOUSE

"The Two Ways of Life, or Hope in Repentance," a composite photograph made from 30 negatives and measuring 31 x 16 in. taken and assembled by Oscar Rejlander in 1857. The elaborate tableau is allegorical, showing a young man torn between a life of debauchery (left portion of picture) and virtue (shown at right)

COMBINATION PRINTS

GEORGE EASTMAN HOUSE

"Fading Away," a composite photograph made from 5 negatives by Henry P. Robinson in 1858. Robinson, like Rejlander, wished to convey the didactic allegories of Victorian painting through the new techniques of photography

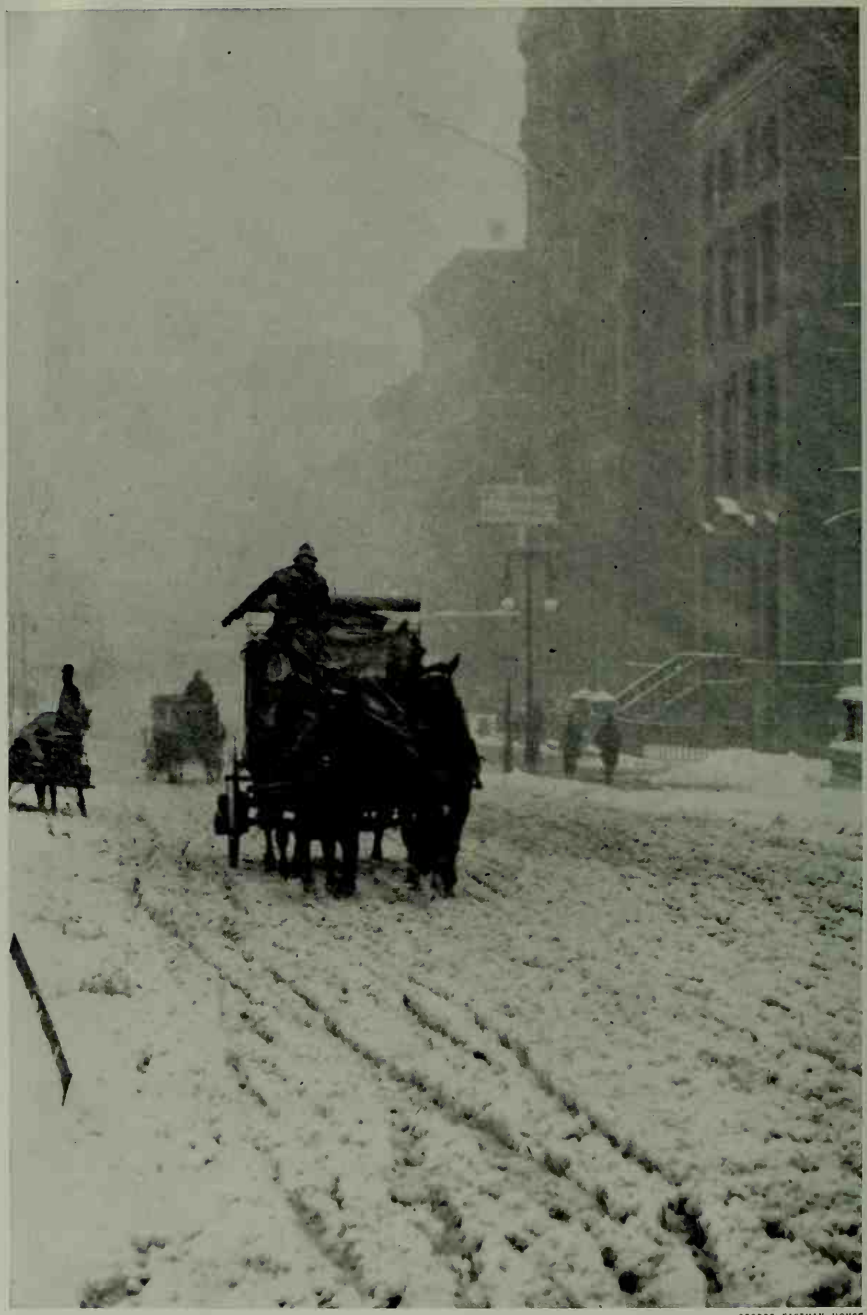
GEORGE EASTMAN HOUSE

"Gathering Water Lilies," a platinum print made in 1886 by Peter H. Emerson, the founder of the naturalistic school; one of his many pictures of life on the East Anglia marshes. Emerson strove to prove that photographers could produce valid works of art without merely copying conventions used in painting

GEORGE EASTMAN HOUSE

BY COURTESY OF THE METROPOLITAN MUSEUM OF ART, BEQUEST OF ALFRED STIEGLITZ, 1949. ALFRED STIEGLITZ COLLECTION

Two portraits by Julia M. Cameron: (left), Sir John Herschel, the astronomer, in 1867, and Ellen Terry, the actress



GEORGE EASTMAN HOUSE

"Winter on Fifth Avenue, New York," 1893, by Alfred Stieglitz, a pioneer in the use of the hand camera and one of the founders of the influential Photo-Secession group

GEORGE EASTMAN HOUSE

"The Octopus, New York" by Alvin L. Coburn, 1912, an early abstraction taken from atop a tall building

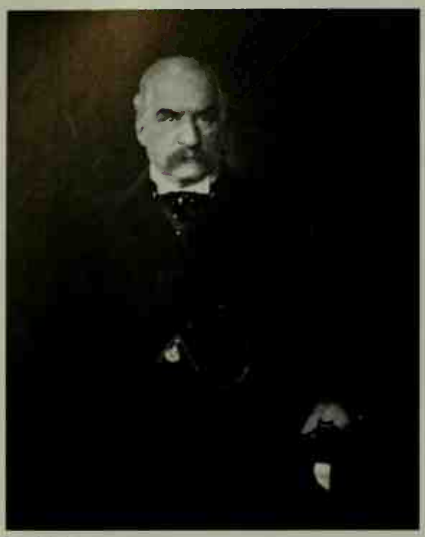
"Photogram" by László Moholy-Nagy, about 1940, an abstract photograph made by placing objects directly on sensitized paper and exposing the paper to light

GEORGE EASTMAN HOUSE

PAUL STRAND

"The Family" by Paul Strand, 1953, one of a book-length series of photographs comprising a profile of the small Italian town of Luzzara

PHOTOGRAPHIC ART

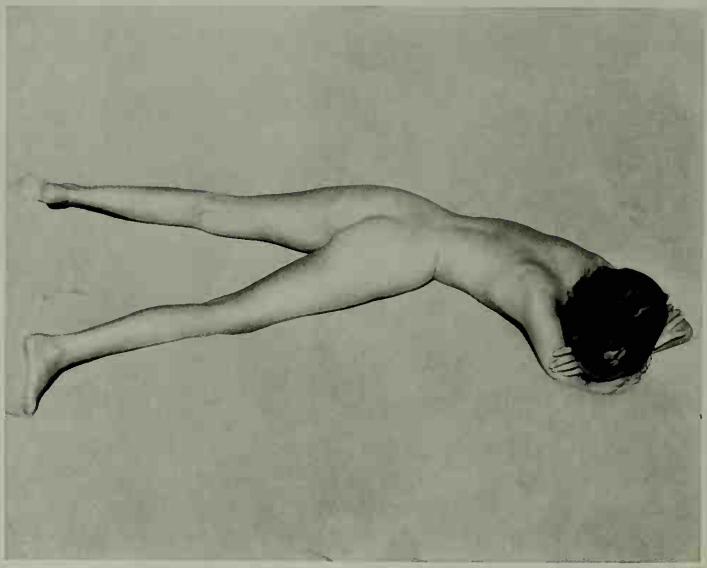


EDWARD STEICHEN

"Portrait of J. P. Morgan," platinum print by Edward Steichen, 1903

BERENICE ABBOT

"The Organ Grinder" by Eugène Atget, a long-neglected French photographer who recorded the look of Paris and its people during the early years of the 20th century



COLE WESTON

"Nude on Beach, California" by Edward Weston, 1936

ANSEL ADAMS

"Moonrise, Hernandez, New Mexico" by Ansel Adams, 1941

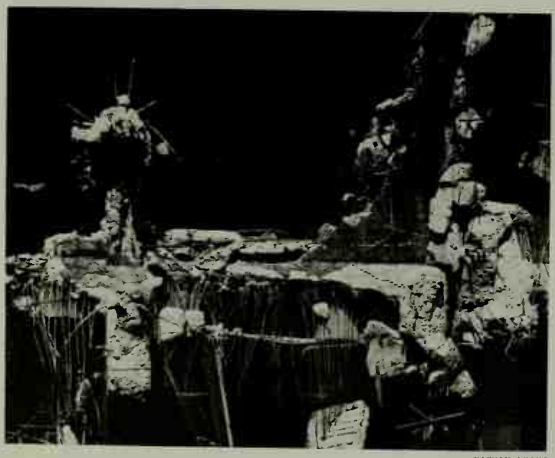
HENRI CARTIER-BRESSON—MAGNUM

"Children Playing in the Ruins, Spain" by Henri Cartier-Bresson, 1933



NATHAN LYONS

AARON SISKIND

Two contemporary abstract photographs: (above) "Demolition, Rochester, 1956" by Nathan Lyons and "Rome 50" by Aaron Siskind, 1963

a greater latitude in reproducing extremes of tone from the strongest to the most subtle and delicate. When a photographer speaks of the warm or cold tone of a print, he is usually referring to its colour—a cold blue-black as opposed to a warm green-black. But to use such variations of colour to emphasize the feeling of his picture is to misuse his medium. If he prints a snow scene blue-black so that it will look cold and a forest scene green-black so that it will appear warm, he is introducing a foreign element into his monochromatic process just as surely as if he coloured the print by hand. In black-and-white photography the effect of warmth or coldness should be communicated by the values in the print, whose colour should—at the extremes of the scale—be as nearly pure black and pure white as possible (use of obvious colour tone belongs in the province of colour photography). Obviously then, the longer scale of glossy paper gives greater opportunity of producing through the values in the print whatever effect is desired. And lastly, the luminous surface of the glossy paper, by making the image light-giving, comes nearer to rendering the effect of the original scene and so heightens the illusion of reality. A good glossy print reveals the delicacy of subtle gradation, the lucidity of tone, and the brilliant clarity of image that are unique characteristics of the photographic process.

Subject Matter.—It is impossible to make any sharp distinction between the subject matter appropriate to one graphic medium and that more suitable to another. But in the case of photography we can at least draw a few general conclusions, based on an examination of the work of the past and our knowledge of the special properties of the medium. From the wet plate era we may draw two contrasting examples that serve to indicate a field of endeavour in which the photographer is least likely to be successful. On the one hand is the work of O. G. Rejlander and Henry Peach Robinson, two men who achieved prominence for their photographic work in England during the 1850s and 60s. In their best-known pictures (Rejlander's "Two Ways of Life," and Robinson's "Fading Away") they attempted to depict allegorical and dramatic situations by combining a number of negatives of posed and costumed figures into composite prints. On the other hand is the work of Roger Fenton, Mathew Brady, Alexander Gardner, and many anonymous photographers who documented wars. These men were bound by no artistic purpose; their sole aim was to record to the best of their ability every phase and aspect of the hostilities that their clumsy and limited equipment could encompass. Yet it is in these straightforward records that we perceive true photographic quality: here is the tremendous power and appeal of the camera's realism, the intensity of its vision undiluted; and these documents of the past still move us profoundly with their clear, objective picture of the horror and pathos of war. Beside these photographs the artistic efforts of Rejlander and Robinson appear self-conscious, stilted, and artificial. Their carefully posed and costumed figures look absurd and unreal.

Now this comparison makes one fact apparent: the camera lens sees too clearly to be used successfully for recording the superficial aspects of a subject. It searches out the actor behind the makeup and exposes the contrived, the trivial, the artificial for what they really are.

But if the camera's innate honesty works any hardship on the photographer by limiting his subject matter in one direction, the loss is slight when weighed against the advantages it provides. For it is that quality that makes the camera expressly fitted for examining deeply into the meaning of things. The discriminating photographer can direct its penetrating vision so as to present his subject—whatever it may be—in terms of its basic reality. He can reveal the essence of what lies before his lens in a close-up with such clear insight that the beholder will find the recreated image more real and comprehensible than the actual object.

The photograph isolates and perpetuates a moment of time: an important and revealing moment, or an unimportant and meaningless one, depending upon the photographer's understanding of his subject and mastery of his process. The lens does not reveal a subject significantly of its own accord. On the contrary, its vision is completely impartial and undiscriminating. It makes no distinction between important detail and meaningless detail. Selection, emphasis, and meaning must be provided by the photographer in his composition. Nowhere has the painter's influence had a more lasting hold on photography than in the field of composition. Photographers who have put to use every other resource of their medium still try to emulate the work of painters in this respect. They consider composition as a thing apart, having no relation to a specific medium, but consisting of a set of tested rules and conventions that must not be contravened. To compose a subject well means no more than to see and present it in the strongest manner possible. The painter and the photographer will have two different ways of doing this because of the basic differences between their mediums. Its capacity for rendering fine detail and tone makes photography excel in recording form and texture. Its subtlety of gradation makes it admirably suited to recording qualities of light or shadow, and its ability to record sharply everything within the angle of lens vision from the immediate foreground to the distant horizon carries it far beyond the painter's province. The photographer cannot depend on rules deduced from finished work in another medium. He must learn to see things through his own eyes and his own camera; only then can he present his subject in a way that will transmit his feeling for it to others.

An intuitive knowledge of composition in terms of the capacities of his process enables the photographer to record his subject at the moment of deepest perception; to capture the fleeting instant when the light on a landscape, the form of a cloud, the gesture of a hand, or the expression of a face momentarily presents a profound revelation of life.

The appeal to our emotions manifest in such a record is largely due to the quality of authenticity in the photograph. The spectator accepts its authority and, in viewing it, perforce believes that he would have seen that scene or object exactly so if he had been there. We know that the human eye is capable of no such feat, and furthermore that the photographer has not reproduced the scene exactly; quite possibly we would not even be able to identify the original scene from having seen the photograph. Yet it is this belief in the reality of the photograph that calls up a strong response in the spectator and enables him to participate directly in the artist's experience.

Conception and execution so nearly coincide in this direct medium that an artist with great vision can produce a tremendous volume of work without sacrifice of quality. But the camera demands for its successful use a trained eye, a sure, disciplined technique, keen perception, and swift creative judgment. The artist who would use his photographic powers to the full must have all these, plus the first requisite for the artist in any medium—something to say.

(E. WN.)

PHOTOGRAPHY is the process or art of producing visible images (photographs) on sensitive surfaces directly or indirectly by the action of light or other form of radiant energy. Classical photography depends on the action of light in bringing about changes in compounds of silver, usually the silver halides (*e.g.*, silver bromide, silver iodide, and silver chloride). These changes may be a directly visible darkening (print-out) or, more generally, may be invisible (latent image); in the latter case a developer must be applied to reveal the image. The act of permitting the light to fall on the sensitive layer is known as exposure. The developer is a chemical reducing solution that converts the exposed silver halide to dark, metallic silver.

Usually, the brighter the subject is the darker the photograph is, so that a negative picture results. In order to obtain a positive picture, in which the light and dark parts correspond to those of the original scene, the negative is printed onto another sheet of sensitive material that basically resembles the negative material, so that the tones are reversed on the second sheet. If the positive is made in the original negative material by developing the negative, removing the negative silver by chemical means (bleaching),

and then developing the remaining material, the procedure is called the reversal process. Positives may be produced directly in the originally exposed material by using special effects such as solarization and the Herschel effect.

The sensitive layer usually consists of tiny particles of compounds of silver dispersed in gelatin and coated in a layer (usually less than $\frac{1}{1,000}$ in. thick) on a support consisting of rigid glass, flexible film, or paper. An example of a sensitive layer is silver bromide in gelatin. After it is exposed to light it can be developed to black silver, the degree of blackening depending on the extent of exposure. Treatment with a solution that dissolves the remaining silver bromide but does not attack the silver fixes the negative or positive and renders it stable against further exposure, after it has been washed in water.

The operations required to produce a photograph are these:

1. Preparation of the sensitive negative material.
2. Exposure.
3. Development, followed by fixation, washing, and drying.
4. Preparation of the sensitive positive material.
5. Printing.
6. Development, fixation, washing, and drying of the print.

FIG. 1.—STEPS IN THE PRODUCTION OF A PHOTOGRAPH

In the early days of photography all of these operations were carried out individually by the photographer himself, but at the present time the sensitive materials, both negative and positive, are almost always made by manufacturing companies, and much of the developing and printing is done by commercial organizations.

A wide variety of negative materials, cameras, and printing processes are used in photographic operations, their selection depending upon the particular branch of photography under consideration.

I. HISTORY

Discovered by no one man, photography is the outcome of the early observations by physicists of the formation of images in the camera obscura and by chemists of the action of light, sub-

jects that in truth belong to the domain of photo-optics and photochemistry (*q.v.*). Although the blackening of silver salts was known in 1565, it was not until 1725, when J. H. Schulze used a mixture of silver nitrate and chalk under stenciled letters, that it was definitely recognized that this darkening action was caused by light and not by heat. The experiments were repeated by William Lewis in 1763 and Joseph Priestley in 1772 and were greatly extended by C. W. Scheele in 1777. Their work led to Thomas Wedgwood's experiments with silver nitrate on paper and leather, the results of which were published in 1802. Humphry Davy suggested that silver chloride would be more sensitive to light, but all early efforts to make pictures with the camera obscura failed because of the very long exposures required, and because no means were known by which to remove the unaffected material and thus stabilize or "fix" the image against light.

1. Camera.—The camera was the outcome of the old camera obscura, originally a darkened room with a tiny hole in the window shutter for viewing natural scenes, the invention of which has been incorrectly ascribed to Giovanni Battista della Porta, who in his *Magia naturalis* (1558) published a long and clear description of it. The principle had, however, been known to Alhazen (*c.* 1000), Roger Bacon (*c.* 1267), and others; and the camera obscura itself had been described by Leonardo da Vinci (d. 1519) in his notebooks, which remained unpublished until 1797. In 1550 Geronimo Cardano proposed the addition of a biconvex lens to obtain a brighter image. Daniello Barbaro in 1568 suggested the use of a diaphragm to secure greater sharpness. Ignazio Danti in 1573 corrected the reversed image by means of a concave mirror behind the lens, a device still in use. Friedrich Risner (d. 1580) described in his works (published 1606) methods of enlarging and reducing the image, and proposed that a portable box be used in lieu of the room in use until then. Della Porta, in his greatly enlarged second edition of the *Magia naturalis* (1589), included all the improvements of others as his own. Johannes Kepler in his work on optical astronomy, 1604–11, described the use of a concave lens behind the convex to obtain larger images, and thus anticipated the telephoto lenses of the present day. In a book published in 1685–86 Johann Zahn described a portable camera obscura with two or three lenses mounted in a tube to secure a more brilliant image on a ground glass, and side wings to shield it from extraneous light. At the beginning of the 18th century the portable camera obscura had become a regular article of commerce and was used to obtain sketches from nature. Its use was stimulated by the growth in the number of amateur artists, who also used other optical devices, such as the camera lucida and the Claude glass, as aids in sketching.

The ineptitude of the artists led to an interest in letting light from the scenes create its own record, particularly through the medium of the camera obscura. Photography thus grew from attempts to apply to the interests of picturemakers observations on the action of light in producing visible changes.

EARLIEST EXTANT PHOTOGRAPH BY J. NICÉPHORE NIEPCE OF THE VIEW FROM HIS WINDOW AT GRAS, NEAR CHALON-SUR-SAÔNE, FRANCE. FIXED ON A PEWTER PLATE IN 1826

2. The Beginnings of Photography.—Toward the end of the 18th century there grew a demand for inexpensive naturalistic pictures, particularly portraits. A simple way of producing pictures was the silhouette, made by tracing the outline of a projected image of the face and filling it in with black. In 1786 G. L. Chrétien invented the "physionotrace" in which the projected image of a head was traced by a stylus, and by a pantograph arrangement an engraving tool cut a copper plate which could be inked and printed. Aloys Senefelder invented lithography in 1798; but, though it was introduced in Paris in 1802, it was not until 1813 that it became a success and a fashionable hobby. From that date until 1817 Joseph Nicéphore Niepce was engaged in an examination of natural stones to find one suitable for lithography. Since he was unable to draw, his son, Isidore, undertook this work, and when the latter was called for military service, Niepce was impelled to produce the images automatically. In conjunction with his brother Claude, Niepce first tried photography with silver chloride on paper. The light sensitiveness of iron, manganese, acids, and other compounds was tested, stone, metal, and paper being used as supports. Finally, guaiacum resin was tried and then asphalt, or bitumen of Judea, which had been in common use as an etching ground since the days of Rembrandt. This, becoming insoluble in its usual solvents by the action of light, gave not only a resist for the etching of metal plates but also transparent images on glass. A successful result—a photographic copy of an engraving without use of the camera—was obtained in 1822, and thus it may be said that the first permanent photograph was made in that year by Niepce. Prior to that, in 1816, Niepce had obtained in the camera a positive on paper.

BY COURTESY OF THE GERNSHEIM COLLECTION, LONDON

DAGUERREOTYPE OF L. J. M. DAGUERRE TAKEN IN 1848 BY J. E. MAYALL

Three years were required to perfect the process of heliography, as it was called, by the simple superposition of waxed engravings; and in 1826 an etched pewter plate was sent to G. Lemaître, of Paris, to be printed. In order that the pictures should be more distinct, they were exposed to the vapours of iodine. The highlights of the plates consisted of hardened bitumen; the shadows, of the bare metal; thus, the contrasts were very poor. This led to the use of pewter instead of copper. Lemaître suggested silvering copper plates. Between 1816 and 1829 Niepce also fixed the image in the camera several times using silver compounds and the bitumen process. In 1827 he submitted to the Royal Society, London, his first successful view from nature, taken in the camera obscura with an exposure of over eight hours, together with a memoir on heliography.

3. Daguerreotype.—In 1826 L. J. M. Daguerre, a painter who had experimented with silver salts, heard of Niepce's work and approached him to form a partnership. This was consummated in December 1829. The work that Daguerre had done with Niepce had drawn their attention to the light sensitiveness of silver iodide, and Daguerre discovered that the effect produced by exposing an iodized silver plate in a camera would result in an image if the plate were fumed with mercury vapour and fixed in a solution of common salt. The inventions of Niepce and Daguerre were published simultaneously by the French home minister in a bill presented to the Chamber of Deputies proposing a national reward to the inventors. A full description of their methods was presented by François Aragn on Aug. 19, 1839, at a joint meeting of the Académie des Sciences and of the Académie des Beaux Arts.

The daguerreotype process was a complete success. In its operation, a silvered copper plate was buffed and burnished to a high polish. It was then iodized by fuming with iodine, and exposed in a camera for 20–30 minutes, which excluded portraiture. After various optical and chemical improvements by American, English, and Austrian investigators, from 1841 onward exposures were secured in a few seconds under favourable light conditions. The development was effected by placing the exposed plate over a cup of mercury heated to about 75° C. The image was then fixed with a solution of thiosulfate of soda and strengthened by treatment with gold chloride. The daguerreotype was viewed by reflected light and was laterally reversed, and copies could only be obtained by copying the original picture. The process flourished, especially for portraiture, until about 1860. England was the only country in which it had been patented.

4. Calotype.—A preliminary notice of Daguerre's success was made by Arago on Jan. 7, 1839. This caused W. H. Fox Talbot,

BY COURTESY OF MATILDA TALBOT AND HAROLD WHITE

FOX TALBOT'S CALOTYPE ESTABLISHMENT AT READING, ENG., ABOUT 1845

Assistants photographing a painting and making a portrait

an Englishman, to claim priority in obtaining a picture in the camera and rendering it permanent. Talbot had begun his experiments in 1834, using the camera obscura with silver chloride on paper and common salt or potassium iodide as fixing agents. A communication was made to the Royal Society on Jan. 31, 1839. But not until a month later did he disclose his working method of "photogenic drawing," which then involved silver iodide with an excess of the nitrate, and fixation with sodium thiosulfate. The solvent action of this for silver salts had been discovered by Sir J. F. W. Herschel in 1819. Exposures were 30 minutes to one hour in the camera until June 1841, when Talbot announced the much faster, patented, calotype process in which the latent image was developed with gallic acid, the accelerating action of which had been discovered independently by the Rev. J. B. Reade.

The developed image on calotype paper was the exact reverse, as far as light and shade were concerned, of the original image. Such a picture was termed by Herschel in 1840 a "negative." The transparency of paper can be increased by waxing or oiling, and so Talbot was able to obtain true copies, or positives, of any negative by simple contact printing upon another piece of sensitized paper. Talbot's process is the first step in the real line of photographic development, the inventions of Daguerre and Niepce being bypaths whose chief importance was the stimulus they gave to photographic evolution. The disadvantages of calotype were the long time required for printing and the structure of the paper.

Herschel in September 1839 took a photograph on glass coated with carbonate of silver. In 1848 Abel Niepce de Saint-Victor suggested albumen as the vehicle for silver iodide. This albumen-on-glass process was very slow but held its own until 1851, when Frederick Scott Archer, an English sculptor, published a description of his wet collodion process.

5. Collodion Process.—To a solution of cellulose nitrate (collodion) in ether and alcohol, Archer added a soluble iodide, usually with the addition of a little bromide, and coated a glass plate with it. In the darkroom, the iodized collodion was sensitized by immersion in a bath of silver nitrate and formed silver iodide with an excess of silver nitrate. The plate was exposed wet in the camera, developed by pouring on a solution of pyrogallol containing acetic acid, and fixed with a strong solution of thiosulfate of soda for which potassium cyanide was later substituted. Archer's collodion process was not patented, and as it was the fastest photographic process it displaced by the mid-1850s both calotype and daguerreotype. For portraiture, a modification of the process was devised by Archer and P. W. Fry. An underexposed negative backed with black paper or velvet appeared as a positive and was very popular for cheap portraiture under the name Ambrotype.

BY COURTESY OF GEORGE EASTMAN HOUSE

AMBROTYPE WITH BLACK BACKING ON ONE HALF TO SHOW ITS NEGATIVE-POSITIVE CHARACTER

The necessity for preparing the plates immediately before exposure and developing them immediately after considerably limited the practice of photography. John Spiller and William Crookes suggested bathing the prepared plates in a solution of a hygroscopic salt so that they could be kept some time both before and after exposure. This was followed by the use of hygroscopic substances of all kinds. They greatly reduced the speed of the plate, however, and were of little practical value.

6. Collodion Emulsion.—In 1864 B. J. Sayce and W. B. Bolton described the preparation of an emulsion of silver bromide in collodion. In 1874 Bolton washed the emulsion in bulk to remove the soluble salts formed in precipitating the silver bromide, and his methods are still followed.

Collodion emulsion, though it was no more sensitive, was a practical advance over wet collodion. A considerable increase of sensitiveness was obtained when C. Russell introduced alkaline development in 1862, but the full fruit of this was reaped only with the introduction of gelatino-silver bromide dry plates.

7. Gelatin Emulsion.—In 1871 R. L. Maddox made an emul-

BY COURTESY OF GEORGE EASTMAN HOUSE

sion of silver bromide in essentially the same manner as that used for making collodion emulsions but he substituted gelatin for collodion. The matter was followed up by other experimenters, who greatly improved and speeded up the emulsion. Among them must be mentioned John Burgess, Richard Kennett, and Charles Bennett. Kennett placed on the market a dry, washed emulsion which photographers could dissolve in warm water and use as a coating on glass and thus produce their own plates.

A great amount of experimental work was at once commenced on gelatin emulsions, the records of which filled the photographic journals between 1873 and 1885. The by-product salts were removed by washing. William Abney recommended the use of iodide in small quantity with the bromide and found that this made it possible to obtain faster emulsions with less fog. Digestion, or "ripening," as it was called, came into use in 1878, and in 1879 Désiré van Monckhoven employed precipitation in ammoniacal solution as the basis of manufacturing dry plates. In 1877 the commercial plates of the Liverpool Dry Plate and Photographic Printing Company, Wratten and Wainwright, and B. J. Edwards were introduced. By 1879 comparatively rapid dry plates were available on the market.

After this period, amateurs gradually ceased their researches, and mass manufacture became general. Considerable increases in sensitiveness were made by improved emulsion-making techniques which resulted in further advances in sensitivity without the undesirable qualities which previously had accompanied attempts to increase speed.

8. Colour Sensitivity.—The silver halides are sensitive chiefly to the blue, violet, and ultraviolet rays; hence, all other colours are reproduced as dark grays or blacks. In 1873 H. W. Vogel of Berlin discovered that the addition of certain dyes to the emulsion, or immersion of the coated plates in a solution of dye, increased the sensitiveness to other colours.

Following this, J. Waterhouse found that eosin sensitized collodion emulsion, and shortly afterward John Clayton and P. A. Attout found that eosin would sensitize gelatin emulsions. They obtained a patent for its use in England and France, and their plates were placed on the market under the name of "isochromatic" plates. In 1884 eosin was replaced by erythrosine, which was found by Joseph M. Eder to be a better sensitizer, and for 50 years erythrosine was used almost exclusively for the so-called "isochromatic" or "orthochromatic" materials. In 1903 Adolf Miethe and Arthur Traube found that ethyl red, an isocyanine dye, gave strong colour sensitiveness as far as the orange of the spectrum, and in 1905 B. Homolka discovered Pinacyanol, a dye of structure somewhat similar to ethyl red but which sensitizes very powerfully throughout the red. It thus became possible to make "panchromatic" plates, which would photograph the entire visible spectrum without difficulty. Such plates were placed on the market in 1906 by the English firm Wratten and Wainwright.

The early dyes were largely of the cyanine and isocyanine types. In 1920 W. H. Mills and F. M. Hamer found Pinacyanol to be a carbocyanine dye. After that time there was much activity in the study of sensitizing dyes, resulting in the present great variety which achieve high sensitivity in all parts of the visible spectrum and out into the infrared. Most of the new dyes were found after 1929 in England, Germany, and the United States, and the most important types are modifications of the carbocyanines and the merocyanines.

The first panchromatic film was made by the Eastman Kodak Company in 1914, but it was not generally used for motion-picture work until 1925. In 1931 a new supersensitive type of panchromatic film was introduced. The progress in sensitizing dyes made possible the great advance in colour photography after 1930 and the introduction of plates and films of high speed and low graininess.

9. Film.—The weight and fragility of the glass support led to attempts to replace it by lighter and flexible substitutes. In 1875 Leon Warnerke introduced a roller slide containing a spool of stripping film for 100 exposures. Ten years later the roll film system of photography was popularized through mass manufacture by George Eastman and W. H. Walker. A machine for continuously coating photographic paper in long rolls was patented by Eastman in 1884. The sensitized paper was loaded into a roll holder which could be attached to the back of a camera in the same position as a plateholder. At first, the paper was greased to reduce the printing time, but later a stripping film was used. This consisted of a temporary paper base coated with soluble gelatin, which in turn was coated with a gelatin emulsion.

This stripping film was used in the first portable roll film camera, the No. 1 Kodak, marketed in 1888. The pictures were circular, about $2\frac{1}{2}$ in. in diameter. When the film was used up, the camera was returned to the manufacturer, who developed and printed the pictures and reloaded the camera. This was the origin of modern photofinishing.

Eastman conducted experiments to produce a flexible film from collodion, but the ether-alcohol solutions would give only films that were too thin to be of practical use. Finally, the use of wood alcohol as a solvent for nitrocellulose was discovered, and a flexible film was marketed in rolls in 1889. In the previous year J. Carbutt had introduced emulsion coated on sheets of plastic nitrocellulose cut from blocks. The new flexible Eastman film was utilized immediately by Thomas A. Edison. The film had been independently invented, and a patent applied for in 1887, by the Rev. Hannibal Goodwin.

In 1891 daylight loading film was made. The film was wound on a wooden core inside a light-tight box and black cloth leaders were attached to the ends of the film. Later, the film was wound inside a protective sheet of black paper; sufficient overlength was left to permit loading of the camera without fogging the sensitive film. In 1903, a noncurling film was produced by coating the back of the film with plain gelatin.

AMERICAN PIONEERS IN PHOTOGRAPHY

THE ORIGINAL NO. 1 KODAK, PERFECTED IN 1888

In 1895 positive film was introduced for printing motion pictures. In 1909 slow-burning motion-picture film was first made by the substitution of cellulose acetate for cellulose nitrate as the plastic used in the preparation of the base.

A method of packing films, invented in 1903, was introduced on the market under the name of "film packs." These are now used mostly in cameras of the type originally designed for plates and sheet film. Flat sheet films have taken the place of plates to a considerable extent, especially in professional photography.

In 1917 X-ray films coated on both sides with emulsion were introduced. Because of the transparency of the material to the X-rays, this doubled the density to be obtained.

The year 1923 marked the introduction of 16-mm. cellulose acetate motion-picture film packed in such a manner that it could be loaded into small motion-picture cameras without the use of a darkroom. This film was designed for finishing by a reversal process, in which the first negative is removed by a bleaching bath and a positive is then developed in the remaining silver bromide. In 1932 a similar film 8-mm. wide was introduced. The use of these films led to a great advance in amateur cinematography.

10. Developing Agents.—In the calotype process gallic acid was used as the developer, but in 1851 H. V. Regnault of Paris and Justus von Liebig simultaneously discovered the more energetic pyrogallol, which allowed shorter exposures to be given. This was used also at first for wet collodion, though it was later replaced by an iron salt, and for dry collodion plates. Until 1861 free silver nitrate was an important ingredient of developers; but in that year G. Wardley proved that pyrogallol alone could be used. C. Russell and Thomas Leahy independently announced alkaline pyrogallol development, the former suggesting also an alkaline bromide as restrainer. Even after the introduction of the gelatin dry plate, pyroammonia was the only developer used until 1884, when the alkaline carbonates came into general use. In 1880 Abney discovered the developing properties of hydroquinone. C. Égli and Arnold Spiller recommended the use of hydroxylamine in 1884. In 1888 M. Andresen of Berlin patented the use of para-phenylenediamine, para-toluidinediamine, and xylidenediamine as developers. In 1891 he patented the use of para-aminophenol and its derivatives, especially para-methylaminophenol sulfate (Metol, Elon). In 1951 W. B. Kendall and Ilford Ltd. announced a new kind of developing agent, 1-phenyl-3-pyrazolidone, under the trade name of Phenidone. It can be used to replace a great part of the Metol in Metol-hydroquinone developers.

11. Printing Processes.—The first printing process, *i.e.*, Talbot's, employed silver chloride and excess silver nitrate on plain paper, the image being more or less buried in the fibres of the paper. Furthermore, many hours of daylight were essential for printing. Louis Désiré Blanquart-Evrard in 1847 suggested the use of albumen to keep the sensitive salt more on the surface. A few years later the first coat of albumen was coagulated and a second applied, which gave a more brilliant glossy surface. The colour of prints obtained on this printing-out paper was yellow and to darken the colour to a deep sepia Gustave le Gray in 1850 proposed toning the print with chloride of gold which had been the standard practice with daguerreotypes since 1841. Albumenized paper toned with gold remained the standard photographic printing medium until about 1900. It was too slow for enlarging purposes.

Alexis Gaudin had suggested an emulsion of silver chloride in collodion for printing-out. This was revived by George Wharton Simpson in 1864. Paper thus prepared was introduced commercially by J. B. Obernetter four years later. Humbert de Molard, 1855, proposed to precipitate silver chloride, wash and suspend it in a solution of starch or gelatin, and paint the mixture onto paper. The same process was revived by W. H. Smith and J. E. Palmer in 1865 and by Abney in 1882. From that date gelatinochloride, or printing-out, paper came into general use and eventually completely displaced albumen. Printing-out papers are little used now except for proofs.

Gelatin silver bromide paper was invented and first produced in 1873 by Peter Mawdsley, founder of the Liverpool Dry Plate & Photographic Printing Company. Six years later J. W. Swan of Newcastle patented it and by 1880 several firms had begun its manufacture in England. In 1881 J. M. Eder and G. Pizzighelli published a paper on gelatinochloride of silver with development, and the former, two years later, described a chlorobromide emulsion. Chloride developing paper was introduced by Marion and Co. in England under the name of Alpha in 1884 and by the Nepera Chemical Co. in the United States as Velox nine years later. Since then the use of this paper has increased, special types, including a great variety of surfaces, being used for amateur and professional work. Modern papers are of the chloride type for contact printing, and of the bromide and chlorobromide types mainly for enlargements. Special papers are made for industrial and scientific use, document reproduction, graphic arts, and photofinishing.

12. Nonsilver Printing Processes.—The gradual fading of silver prints led many experimenters to the investigation of different light-sensitive substances promising permanence. Robert Hunt utilized the light sensitiveness of ferric oxalate in combination with a platinum salt in the hopes of obtaining images in that metal, but the process was a failure because he did not recognize that the ferrous salt, formed by the action of light, must form a complex in order to reduce the platinum salt to the metal. William Willis of London in 1873 patented a workable platinum process, but it was not until 1879 that platinum paper was put on the market. The pictures are permanent but the high cost of platinum and the ease with which development papers are worked resulted in neglect of the process after World War I.

Louis Vauquelin in 1798 had discovered the light sensitiveness of silver chromate; G. I. Suckow in 1832 observed that the bichromates were reduced by light in the presence of organic matter. Mungo Ponton in 1839 used paper treated with potassium bichromate. Edmond Becquerel in 1840 and Robert Hunt in 1843 made improvements; but Talbot first pointed out in 1852 that bichromated gelatin became insoluble on exposure to light, and this was patented as a resist for photogravure, for which it is still used.

Paul Pretsch, Alphonse Poitevin, Testud de Beauregard, Henri Garnier, and A. Salmon and John Pouncy devised carbon processes in which carbon in a finely divided state was used as the pigment in bichromated gelatin. But they failed to recognize the important point that, as the light acted first on the outer surface of the gelatin, those parts underlying the middletones and highlights would still be soluble; hence, on developing with warm water, they would have no anchorage to the support and would be washed away. J. W. Swan in 1864 patented the production of carbon, or pigment, prints by transfer of the exposed pigmented tissue to a temporary support on which it was developed from the back. A few months later Walter Bentley Woodbury of London patented a photorelief printing process, called Woodburytype, which produced very similar permanent photographs to the carbon process.

Working on principles published by Alphonse Poitevin in 1855, A. Rouillé-Ladêveze in 1894 introduced the gum print process

which after further improvement by R. Demachy the following year became the favourite medium of pictorial photographers until the 1920s. T. Manly in 1905 patented Ozobrome, a pigment process in which a developed silver print was squeegeed into contact with pigmented tissue saturated with potassium ferricyanide and bichromate. A modification of this, known as Carbro, was introduced later.

In 1905 G. E. Rawlins reverted to an old process suggested by E. Mariot in 1866. Gelatinized paper is sensitized with bichromate, dried, exposed under a negative, freed from excess salt, and inked up with a greasy ink, which adheres only to the light-affected parts. Somewhat similar is the bromoil process, first suggested in 1907 by E. J. Wall and worked out by Welborne Piper. This utilizes the principle, stated by Howard Farmer in 1889, that finely divided silver imbedded in gelatin reacts with bichromates and renders the contiguous colloid insoluble. A bromide print is treated with a hardening and bleaching solution, fixed, washed, and dried, then soaked in water and inked up with a greasy ink, which takes only on those parts where there was silver.

A number of printing processes have depended upon the light sensitivity of salts of iron. The most used until after World War II was the blueprint process for copying drawings, introduced by Herschel in 1842. Paper is sensitized with a mixture of potassium ferricyanide and ferric ammonium citrate. On exposure to light the latter is changed to the ferrous compound which, on wetting the paper, combines with the ferricyanide to form Prussian blue. In the ferrogallic process the exposed iron salts are developed in gallic acid to give a positive image in dark ink. The ferrous salts formed by exposing ferric compounds to light can reduce other metal salts to the metal. Platinotype depends essentially on this reaction, but in the argentotype (Herschel, 1842) and kallitype (1889) and the more recent Vandyke processes, a silver image is formed by reduction of silver nitrate by the ferrous salt. In the ferrogelatin process (A. Tellkampf and Arthur Traube, 1905; also known as fotol, Ordoverax, fulgar) an unwashed blueprint is squeegeed in contact with a moist gelatin surface, then removed, and the surface rolled with greasy ink, which gives a positive image that can be transferred to paper.

Light-sensitive organic compounds have formed the basis of many printing processes, the most used being the diazotype process for copying drawings (G. Kögel, 1917, 1920). In it, paper is coated with diazo compounds that are destroyed on exposure to light, development being with a "coupler" that combines with the unexposed diazo compound to form a dye.

In the metal-diazonium process, higher sensitivity is obtained than in the normal diazo process. On exposure to ultraviolet, certain diazo compounds give decomposition products that can reduce some metal salts, *e.g.,* mercurous nitrate, to the metal if the compounds are coated together. The small particles of metal formed, *e.g.,* mercury, can be physically developed in a solution of silver salts and a reducing agent to give a dense image of high contrast and high resolving power.

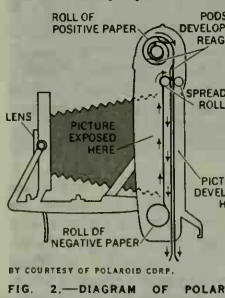
Photosensitive glass was described by S. D. Stookey and the Corning Glass Works in 1947. Coloured images can be produced in special glasses by exposure to ultraviolet followed by heating. Silicate glass is used, but it contains ultraviolet absorbers, optical sensitizers, and photosensitive metals such as gold, silver, and copper. In 1951 a new photosensitive glass was announced in which exposure to ultraviolet followed by heat treatment increased very greatly the solubility of the glass in hydrofluoric acid so that relief patterns could be etched into the glass.

Photothermography provides a dry method of copying documents relying on reactions initiated by heat and giving a directly-visible image. In the Thermo-Fax process, documents are copied by reflex, using a source of infrared radiation. The rays absorbed by the dark image areas of the original document are converted into heat which affects locally the coating of a sheet of material in contact with it. Originally, a layer of wax was used and was caused to melt into a paper supporting layer having a coloured opaque backing. Later a chemical reaction between colour-forming components in the coating was initiated imagewise by the local heating. In 1950 there was introduced on the American market equipment for an electrophotographic process—xerography—which is a dry, indirect process of photographic reproduction. It depends on the action of light in discharging a uniformly charged photoconductive insulating layer on a conductive support, such as selenium on a sheet of aluminum. The resulting electrostatic image is "developed" by applying a finely divided dark pigment on a charged carrier so that the pigment will adhere to the charged areas on the layer. This pigment can then be transferred to a receiving sheet, such as paper or a lithographic plate, and fused on by heating. In the Electrofax process, announced in 1954, a photo-conductive layer consists of zinc oxide in an insulating resin binder, on a paper base. The sheet is uniformly charged electrically, discharged imagewise by exposure to the document to be copied, powdered with a pigment which adheres to the remaining charged areas, and fused directly onto the zinc oxide-coated paper.

Some processes have been devised in which the image is produced in a transparent layer by releasing bubbles of gas which scatter light and so give a white image by reflected light and an image of appreciable optical density by transmitted light. Such a system is the Kalfax or Kalvar process, in which diazo compounds are incorporated in a transparent resin layer. On exposure to ultraviolet radiation, nitrogen is released, and when the layer is then heated the gas bubbles expand and form a scattering "bubble" image. Other processes depending on the release of gas have been proposed for producing a relief for braille and for relief printing plates.

Photosensitive polymers have been used, mainly to make "resists" for printing plates, printed circuits, and chemical etching systems. These materials can be coated on metal and other surfaces, using specific solvents, and on exposing the coatings they "polymerize" to become insoluble in the normal solvents. The unexposed areas may thus be dissolved out leaving an "image" in the insoluble polymer which can act as an ink-carrying area in lithography, or as a "resist" against the etching of the metals on which it is left, to provide the relief printing plates in photoengraving, printed circuits, and so on.

Image Transfer Processes.—Image transfer processes have assumed much importance for document reproduction and for continuous-tone photography in the camera. Basically there are two systems, which can be distinguished as diffusion transfer and physical transfer. The diffusion transfer process appears to have been described almost simultaneously in Europe by A. Rott of the Gevaert Company and E. Weyde of the Agfa Company, in 1944, and papers under the names of Geva-copy and Copyrapid respectively appeared on the market for document copying. In the United States, E. H. Land in 1947 adapted a diffusion transfer process for obtaining paper prints rapidly in the Polaroid Land camera. The physical transfer processes are represented commercially by the Verifax system introduced by the Eastman Kodak Company in 1952.



BY COURTESY OF POLAROID CORP.

FIG. 2.—DIAGRAM OF POLAROID LAND CAMERA IN WHICH THE DEVELOPMENT IS PERFORMED AND PRINT PRODUCED BY SOLVENT TRANSFER

In the diffusion transfer process, the negative is developed in the presence of a solvent for silver halide. This not only develops the negative, but also dissolves the nondeveloped silver halides. In contact with the negative layer is another sheet coated with a material such as gelatin containing nuclei for physical development. The silver halides dissolved out of the negative sheet are physically developed onto the adjacent sheet to give a positive image in silver. Many variations are possible, for instance, the developing agent may be in the emulsion of the negative layer and the silver halide solvent in the receiving layer. In the Polaroid Land camera, the combined developing-fixing solution is contained in a "pod" which bursts under pressure in the camera and spreads

the processing chemicals in a thin layer between the exposed negative material and the receiving paper (or film) as they are wound on together. This principle has been applied to colour photography.

The diffusion transfer method is used in the Kodak Bimat system introduced in 1963. A film (Bimat) coated with a colloid layer containing nuclei and soaked in solvent-developer is wound in contact with the camera film after exposure. A negative is developed, with a corresponding positive transparency in the Bimat web.

In the Verifax system using physical transfer, the material exposed in the printer is of paper coated with an unhardened emulsion containing the developing agent. It is exposed in a special printing box by reflex to the document to be copied, and is immersed in an "activator" which initiates development of the negative. The negative sheet is then pulled out of the apparatus in contact with a receiving sheet to which some of the nondeveloped, unhardened positive image adheres. Dye-forming components may be present to enhance the density. (W. Ck.; H. Ge.)

FIG. 3.—ELEMENTS OF A CAMERA

II. MATERIALS OF PHOTOGRAPHY

Negative materials are made by preparing a precipitate of silver bromide containing a small amount of silver iodide in a medium containing enough gelatin to enable it to be set to a jelly when cooled. This suspension is termed the emulsion. The melted emulsion is coated upon a support that may consist either of glass, in which case plates are produced, or a flexible polymeric sheet material, in which case the product is termed film. After the emulsion is set by chilling and then dried, the material is cut to suitable sizes and packed in light-tight containers. Films are packed as sheet films for use in holders similar to those used for glass plates, roll films protected with paper in special spools or cassettes to make them suitable for loading in daylight, film packs, and long rolls for taking motion pictures.

Cameras are of many varieties, the essentials being a lens to form the image, a shutter to regulate the duration of the exposure, a material holder to carry sensitive plates or film, and a connecting shield to protect the sensitive material from exposure to light other than that which comes through the lens. This is sometimes extensible and then takes the form of a bellows.

The cameras used for various purposes are discussed in the section *Apparatus,* below.

Positive materials may be used for transparencies, in which case they are lantern slides on glass or positive films (especially for motion-picture photography). They are prepared in the same way as negative materials, the emulsion being modified to give the results desired. Usually, however, negatives are printed on sensitized paper. Printing papers are generally coated with a sensitive emulsion prepared either with silver bromide, giving bromide papers, with silver chloride, giving chloride papers, or with a mixture of chloride and bromide to give chlorobromide papers.

At one time, most types of paper were prepared with an emulsion containing free soluble silver compounds and were printed under the negative in strong light until the image was visible; such papers are called printing-out papers. No development was required with these papers. They are now used in trace-recording instruments and for the preparation of proofs submitted by professional photographers to customers.

Many other varieties of printing processes are known and some are used to a large extent in the reproduction of drawings; *e.g.,* the blueprint, diazotype, and Vandyke processes. Others use specially sensitized gelatin or other colloid layers containing pigments, *e.g.,* the carbon and Carbro processes, or gelatin to which pigments may be applied; *e.g.,* bromoil. A high percentage of prints are made by special colour processes.

III. SCIENTIFIC AND APPLIED PHOTOGRAPHY

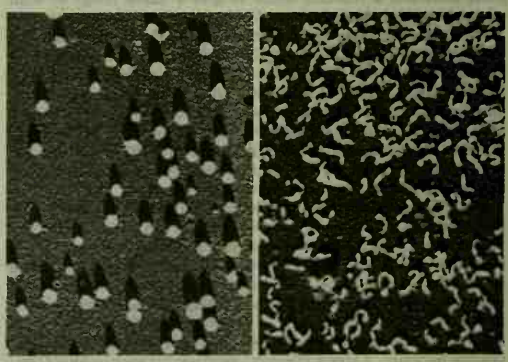
The advantages of photography for scientific and technical recording are that it can record visible images in black and white or colour; it can record radiations of wavelengths invisible to the eye; it can integrate faint radiation and build up a record that can be seen, whereas the eye does not possess this property; it can be used to measure the intensity of radiation; and it can give glimpses of actions that are too fast to be studied in detail by the eye. Moreover, it gives a reasonably permanent record that can be studied at leisure when the original subjects are no longer at hand. Photography thus extends the range of vision, permitting records to be made of things the eye cannot see because they are too faint, are too small, move too fast, or are associated with radiation to which the eye cannot respond.

Photographs themselves are sometimes used as part of a manufactured object (*e.g.,* in the decoration of ceramic articles), as nameplates, instrument dials, electrical wiring diagrams, reticles, and scales. Their most important role, however, is in recording information.

1. Photomicrography.—Photography through the microscope is important in chemical, biological, and geological instruction, but it is especially important in biological research and study; in medicine, criminology, metallography, and petrography; in agriculture, industrial studies, and production control; and in a great variety of fields in which the examination and identification of minute objects or structures is desired. If a slightly enlarged picture, up to about 50 diameters, is adequate, a photomacrograph is made, *e.g.,* of the weave of cloth, of insects or plant stems, or of metal corrosion, using a simple microscope or a single lens with a lens-to-film distance greater than twice the focal length of the lens.

Most photomicrography is done by using the compound microscope with a camera arranged opposite the eyepiece so that the image can be focused on a film or plate. The ordinary hand camera can be used, but photomicrography is best done with a camera without a lens, the microscope and camera being mounted on a rigid bed, vertically or horizontally. Photomicrographs may be made by light transmitted by the specimen or reflected from its surface. The resolution of microscopes will not in general permit the photography of detail finer than 0.2 mμ, although the resolution is increased by using short wavelength radiation; *e.g.,* the ultraviolet. For higher resolution, resort must be to the electron microscope (*see* Microscope).

The usual sources of illumination in photomicrography are carbon arc lamps and incandescent tungsten filament lamps, but for



BY COURTESY OF KODAK RESEARCH LABORATORIES

ELECTRON MICROGRAPHS OF GRAINS IN A "GRAINLESS" LIPPMANN PLATE: (LEFT) UNEXPOSED AND (RIGHT) DEVELOPED

ED HOIS

INFRARED PHOTOGRAPH OF OUTDOOR SCENE

Infrared rays in photography yield peculiar results. They intensify the definition of distant objects, heighten the contrast between light and dark areas, and cause green plants to photograph white, as in the foreground, left.

special purposes flashbulbs, electronic discharge lamps, tungsten and zirconium arcs, mercury-vapour lamps, and sodium lamps are used.

Contrast in photography by transmitted light of stained specimens, such as biological sections or bacteria, is controlled by the use of light filters, maximum contrast being given by filters that transmit light of a colour complementary to that of the stain. Maximum rendering of detail is given by a filter that transmits light of the colour of the stain.

The ultraviolet is used to give maximum rendering of detail. On the other hand, the longer wavelength infrared may be used because some materials are transparent to the infrared while they are opaque to the shorter wavelength. The subjects lie in such fields as histology, cytology, embryology, organic remains in fossils, botanical specimens, and the structure of textile fabrics. Polarized light is used in the photomicrography of birefringent substances, especially in colour. When detail is not rendered satisfactorily by the usual techniques, phase contrast photomicrography may be used with certain subjects. High-magnification motion pictures are often made, using the motion-picture camera in conjunction with the microscope.

Colour photography is important, especially in metallography, polarized-light photography, and the photography of stained sections. Most colour films are suitable, but special attention must be paid to the proper determination of exposure and to the use of filters to ensure correct colour rendering, which is a function of the colour film used, the colour quality of the light source, and colour that is usually present in the optical system of the microscope.

2. Spectrography.—The bulk of spectroscopic observation is done by attaching a camera to the spectroscope and photographing the spectrum. The visual spectrum can be photographed on panchromatic materials and the near ultraviolet on ordinary blue-sensitive plates or films. For wavelengths shorter than 2,800 Å the absorption by the gelatin of the emulsion is too strong to permit photographs to be made, and in this region spectrography is done by coating the plate with a thin layer of material that fluoresces in the short wavelength ultraviolet, fluorescent light being used to make the photograph. In the Schumann method practically all of the gelatin is removed from the emulsion. For the infrared, emulsions containing special infrared sensitizing dyes are used and photographic records have been obtained to beyond 12,000 Å. Plates and films are available having especially high sensitivity in rather narrow wavelength bands spaced all through the visible and near infrared.

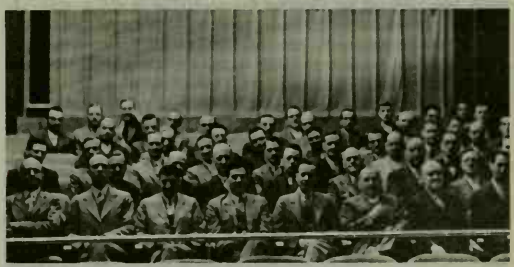
In spectrographic analysis, photographs of spectra are used to detect the presence of elements and to obtain an estimate of the proportions in which they are present. The analyses, qualitative and quantitative, are based upon measurements of the positions and relative intensities of the spectral lines. The method is particularly useful for identifying materials and for determining very small percentages that might be missed or measured inaccurately by chemical methods. (*See* also SPECTROSCOPY.)

The spectrograph has been particularly useful in astronomy since it provides the only means of determining the composition of the celestial bodies. (See *Astronomical Photography*, below.)

3. Infrared Photography.—Plates and films can be made to respond to radiations beyond the red end of the visible spectrum, out to about 13,000 Å, by using special sensitizing dyes. This permits records to be made of subjects that are associated with radiation in the near infrared (spectra, stars, hot objects, etc.) and of subjects that are more transparent to infrared than to visible radiation, or which reflect it differently; *e.g.*, chlorophyll in green vegetation, and hazy atmospheres.

It would not be possible by direct photography to photograph using radiation beyond about 13,000 Å, partly because the atmosphere absorbs strongly in a band just beyond that wavelength and partly because of "dark space radiation," which would affect the films and perhaps even interfere with making the sensitizing dyes.

Infrared photographs over long distances may show greater clarity of far detail, partly because the atmospheric haze may selectively transmit the infrared, and partly because the contrast of the distant objects may be higher as a result of their different reflectivities in the infrared. Chlorophyll is transparent to infrared, and grass and foliage appear white in infrared photographs. Many green paints that match foliage in colour absorb the infrared strongly, so that infrared photography can be used in camouflage detection. The skin is somewhat transparent to infrared and



BY COURTESY OF KODAK RESEARCH LABORATORIES

FIRST GROUP PHOTOGRAPH TAKEN IN TOTAL DARKNESS USING INFRARED FILM, 1931

infrared photography is sometimes of value in medicine in showing the appearance of veins just beneath the skin. It is also of use in dermatology, ophthalmology, and the photography of gross specimens and biological sections. Other applications include photography in total darkness, determination of temperature distribution at the surface of heated bodies, deciphering of altered documents, study of falsified or deteriorated works of art and of textiles, particularly where dark dyes interfere with visual examination, and many applications in botany, paleontology, the graphic arts, criminology, and technology.

4. Ultraviolet Photography.—The invisible ultraviolet rays, shorter in wavelength than visible light, can be used for special photography because the ultraviolet passes through some objects in a manner different from light, and also because it can cause fluorescence in some materials, thus frequently causing photographs made by fluorescent light to reveal details not normally

seen. It is an important tool in the hands of museums and art galleries, police departments, examiners of questioned documents, analytical laboratories, food manufacturers, and mineralogists. In the printing field, original water-colour paintings can be made in fluorescent paints, providing a means of reducing the amount of hand work in the colour separations if a fluorescent photograph is made by ultraviolet.

There are two different methods of ultraviolet photography: (1) the reflected ultraviolet method, which is analogous to ordinary photography except that a filter is used to allow only ultraviolet to reach the film; (2) the fluorescence method, in which the subject is illuminated by ultraviolet and the camera is provided with a filter that absorbs ultraviolet and allows only the visible fluorescent light to reach the film. Normal, orthochromatic, and panchromatic films are used. Colour photography by the fluorescent-light method can be done with ordinary colour films, the choice of film depending on the fluorescing colour it is desired to emphasize.

5. High-Speed Photography.—Photographs made at high speed are very important in science and technology, because they record a phase of a fast event, or photograph a rapid sequence of events that can be slowed down for study. It is necessary to use a very bright light and very short exposure times so that sharp records can be obtained.

The first high-speed photograph was taken by Fox Talbot, using a spark from a Leyden jar. In the 1870s Eadweard Muybridge began his photographic studies of a horse in motion, using successive exposures of short duration in a series of cameras. E. J. Marey, in 1882, perfected a "photographic rifle" in which 12 photographs were taken in one second on a revolving plate. This was called chronophotography, and in 1890 he devised the photochronograph, using film. Similar experiments were made by O. Anschütz in the 1880s. (*See* also Motion Pictures.)

The earliest photographs of projectiles in flight were attempted about the middle of the 19th century at the Woolwich Arsenal in England, by Marey in Paris, and by Anschütz in Germany. A cannonball in flight was photographed at Woolwich in 1866, but the best ballistic pictures were obtained after 1884, when E. Mach, in Prague, introduced the electric spark as the light source. The spark was released by allowing the projectile to cut a wire. L. Bull, Marey's successor in Paris, applied Mach's principle in such a way that he obtained a rate of 2,000 pictures per second. In 1909 C. Cranz made a ballistic cinematograph giving exposures at time intervals of $\frac{1}{5,000}$ sec., for a total time of $\frac{1}{10}$ sec.

Among the early studies of extremely high-speed photography are the photographs of ripples by J. H. Vincent, of splashes by A. M. Worthington, the shadow photography of bullets in flight by C. V. Boys, the analysis of the propagation of flame by Mallard and Henry le Châtelier, and T. E. Stanton's studies of the pressure of gases ejected from nozzles. P. P. Quayle later made improved studies of the flight of projectiles and R. W. Wood of sound waves, outlines of which had accompanied the ballistic pictures of Boys. With a high-speed camera devised by W. Heape and H. B. Grylls, and taking 10,000 pictures a second, studies were made of the penetration of shells into hardened steel targets. Other cameras designed by C. F. Jenkins, Baron Shiba and J. H. Waddell, and the Eastman Kodak and the Bell Telephone laboratories have yielded results of much value in the study of high-speed phenomena. During World War II, high-speed photography was developed and applied to a wide range of studies of military interest, and a great many special high-speed cameras came into use.

The modern methods of high-speed photography may be classed as follows:

Single, Instantaneous Photographs.—(1) Steady illumination and short shutter exposure: the best mechanical shutter will not permit shorter exposures than about $\frac{1}{1,000}$ sec. Special nonmechanical shutters have been developed to give very short exposures in still photography. They include magneto-optical shutters using the Faraday effect; electro-optical shutters using the Kerr effect; electronic shutters using the image-converter tube or the iconoscope.

(2) Light flash of short duration: (*a*) shadow or silhouette, (*b*) reflected light, and (*c*) stroboscopic.

(*a*) In shadow photography, used for objects moving as fast as bullets, the shadow of the object may be cast directly on the film or plate. An electric spark is generally the source, since it is bright, of short duration, and small, thus producing sharp shadows on a film at a fair distance from the spark, if the subject is near the film. Exposures of the order of $\frac{1}{1,000,000}$ sec. may be obtained. Alternatively, a condenser may be used between the spark and the object, the photograph being made in a camera with a lens. A development of this is the Schlieren method, originally used by Léon Foucault and applied by August Toepler, which depends on slight differences of refractive index in the air, or inhomogeneities in glass and other transparent solids. It will show sound waves accompanying the flight of projectiles, convection streams from heated bodies, vortex rings formed in warm air, or vapours of different densities.

(*b*) In the reflected light method, the source is a spark or a lamp of the type of the Edgerton gaseous discharge lamp, the latter with its large area source being preferred on the basis of illumination. A camera is used, as in ordinary photography. This method requires more energy and longer exposure time than the shadow method, but exposures as short as $\frac{1}{50,000}$ sec. can be attained, which is satisfactory for practically all high-speed photography other than ballistics photography.

(*c*) In the stroboscope, a series of light flashes is made to agree with the speed of rotation of a steadily rotating object, so producing a stationary appearance of the object. This can be photographed in an ordinary still camera with long exposures if necessary to record the aspects of the object at any part of its cycle.

Series Photographs.—(1) Motion pictures: The ordinary slow-motion camera takes photographs at 64 frames per second, and some at 128 frames per second. These cameras produce intermittent motion of the film. For higher speeds, up to 5,000 or more frames per second, the film moves continuously and there is compensation for image movement by some optical device such as a rotating plane-parallel glass block, or rings of lenses or prisms. If films made in this way are projected at normal speed, the movement is slowed down to the extent of the ratio of the taking to the projection speeds.

(2) Series of photographs can be made of short duration and at closely successive intervals. In one method, successive photographs are made on one sheet of film by using a rapid series of flashes from a gaseous condenser discharge lamp, or from a series of flashbulbs. In the early studies of animal locomotion by Muybridge, 24 separate cameras, operated in rapid succession, were used.

(3) A special high-speed camera was developed by the Bell laboratories as the ribbon-frame camera, primarily to study the behaviour of rockets in the early part of their flight. The shutter consists of two concentric drums, the outer of which has five slots and the inner four. They are rotated in the same direction, but the outer at 24 revolutions per second and the inner at 30. Glass plates are used to compensate for image movement, and the photograph appears as a series of narrow adjacent strips across the film. A camera developed by F. E. Tuttle is capable of taking 1,000,000 pictures a second; a parallel-line grid is moved in the focal plane in front of the film, and the picture is viewed through a similar grid moving more slowly.

(4) In some cases, as in explosions, the subject is self-luminous, moving fast, and of short duration, and a rapid sequence of photographs of it permits a study of its development. Several methods are used for the study of flame in explosions. In one, short snapshots are made through a rapidly rotating shutter onto a stationary film or plate. If the flame is moving along a transparent tube, a series of such photographs in rapid succession shows the consecutive phases of its propagation. In a second method, the film or plate is moved. If the explosion occurs in a horizontal glass tube, and if it is photographed by a lens on a plate falling vertically or on a film wrapped about a rotating drum, an envelope showing the changing shape of the flame will be obtained, and its velocity can be calculated. In some cameras, rapidly rotating mirrors are used

in the moving film camera to give what amounts to a series of separate snapshots, or the film is held still and a single rotating mirror is used. Exposures shorter than $\frac{1}{50,000}$ sec. can be obtained in this way. Continuous-trace photographs on continuously moving film were used in the study of the initial stages of the explosion of atomic bombs. High-speed X-ray pictures have been taken by discharging a high potential of short duration through an X-ray tube.

6. Astronomical Photography.—Visual observation in astronomy has been replaced almost entirely by photography through the telescope. By using long exposures, photographs can be made of stars that are much fainter than those that can be seen. Many stars can be photographed simultaneously, thereby providing a record of relative positions that may be compared with records made later. Wavelengths not visible to the eye may be used in photography, and careful choice of wavelength may reduce the limitations imposed on penetration into space by the luminosity of the earth's atmosphere. In order to photograph extended areas of the sky, lenses of the type used in ordinary photography or Schmidt lenses are employed. In these, high apertures and short focal lengths are obtained by using a correcting plate in conjunction with a spherical mirror. The small-scale photographs so obtained are valuable for position measurements and surveys, and if the aperture is high enough, faint nebulae, the Milky Way, and meteors may be recorded.

For photographing positions more precisely, or for separating close stars, objectives of longer focal length are used. They are either refractors or reflectors. Refractors suffer from chromatic aberration and are corrected to give their best focus in the green, and the best photographic focus is therefore obtained by using orthochromatic plates and yellow filters. Reflectors do not have this disadvantage. The fastest available photographic plates are used, and the lower definition given by plates of highest speed is not serious since "seeing" limits the sharpness of image the telescope will give. The plates are made so that they have the minimum reciprocity failure for long exposure times.

In addition to direct photography, the other great branch of astronomical photography is spectrography. The chemical and physical constitution of the stars may be determined by the light they emit. Spectra of many stars may be recorded, simultaneously, by placing a prism or grating over the camera objective. Spectral types of many stars may thus be determined in a short time. For more detailed study, the image of the star produced by the telescope is directed to the slit of a spectrograph, and long exposures may be given.

The nearer planets are bright and exposures are relatively short, although fixed by the short time of good observation. Telescopes of short focal length give small bright images, and slow plates may be used. In long-focus telescopes the image is larger but less bright and fast plates must be used. Information about the atmospheres of the planets has been obtained by using plates of different colour sensitivities, relying on the different opacities of the atmospheres to different wavelengths.

Detail of the surface of the sun, the nearest star, is much studied. Direct photography records the positions and areas of sunspots, and the prominences and the corona during eclipses. In times when there is no eclipse, the corona can be photographed by means of the coronagraph. Much information about the sun is obtained from instruments that enable photographs to be made with narrow wavelength bands, in particular the spectroheliograph which uses the red light of the Hα line of hydrogen, or the blue light of the H and K lines of calcium. Birefringent filters transmitting extremely narrow bands of radiation were developed for the same purpose. Motion pictures, speeding up motion, have been made of the moon and the planets, and are regularly made of the sun.

Flare, or the luminous veil resulting from scattered light in the earth's atmosphere, is an important factor in astronomical photography because it tends to obscure faint detail. The intense diffuse light from the sun scattered in the atmosphere prevents the stars from being seen in daytime, but even on moonless nights there is much scattered light and also light emitted by atoms that have been "excited" by sunlight. Observatories are therefore usually on high ground, and as far as possible from cities. In order to avoid the effects of the earth's atmosphere as much as possible, astronomical photography has been done from "platforms," such as balloons, at very high altitudes.

Great advances in astronomy are attributable to improvements in speed and colour sensitizing of photographic plates, and to improvements in fine grain, resolution, and reciprocity failure characteristics. (*See* PHOTOGRAPHY, CELESTIAL.)

7. Criminological Photography.—Photography is one of the most important tools of the criminologist. Its usefulness ranges from straightforward photography of, for example, car accidents and sites of crimes to specialized detective work in deciphering things that cannot be seen. Its scope includes identification records and security passes, fingerprint photography, and photographs in crimes of violence, arson cases, burglaries, and forgeries. Special photographic techniques, such as ultraviolet and infrared photography, aid in detecting stains, invisible writing, and alterations on documents; photography with illumination at glancing incidence may reveal slight depressions or elevations in paper surfaces; multiple printing may be used to enhance very faint contrasts; combination of photography by reflected and transmitted light may yield more information than either alone; spectrographic analysis and radiography are much used; cinematography is used to record criminal operations; photography through the microscope is very important, a special case being the examination of bullets. (*See* also INVESTIGATION, CRIMINAL: *Photography.*)

8. Photoelastic Analysis.—A study may be made of stresses in structures by making models of them in transparent plastics that are isotropic and have large optical stress coefficients. If a stressed model is photographed in polarized monochromatic light, a pattern of light and dark bands results, and from these the distribution of stress may be calculated. The method has been applied successfully to such things as test bars, hooks and chain links, structural foundations, bridge trusses, expansion joints, machine details, and the action of cutting tools. (*See* LIGHT: *Polarization and Electromagnetic Theory.*)

9. Records of Physical Measurements.—Recording in physical measuring instruments can be done by photography where an external spot of light is deflected, for instance, by a galvanometer mirror and falls on a dropping photographic plate or on a moving band of paper or film and records a trace of its path. There are many such devices; *e.g.*, oscillographs, electrocardiographs, seismographs, magnetometers, optical gas engine indicators, and other devices recording variations in pressure, electrical characteristics, optical transmission and reflectance, thickness variations, and so forth. The most-used photographic recording of this type is sound recording, by variable-density or variable-width trace, on motion-picture film.

In trace-recording instruments (other than the cathode-ray oscilloscope), the string galvanometer and the moving-mirror galvanometer are generally used. A much-used type of recording is photography of the trace on a cathode-ray tube. The problems are simple if the trace is recurrent, but if the trace is in the form of a rapid transit that does not repeat, or if the image does not persist, very fast lenses and high-speed films must be used. The films are sensitized to green or have inherent sensitivity to blue, depending on the colour of the phosphor glow. A special adaptation of cathode-ray photography is used to record images on the screens of radar equipment.

10. Photo Layout.—Photographic methods are used for transferring drawings to metal for making templates, precision dials, scales, and wiring diagrams, and for laying out designs for the engineering, aircraft, and shipbuilding industries. Bichromated colloids may be coated on the sheet and developed and the lines darkened by ink or dye. A variation used a sensitive colloid containing the pigment but gave a direct positive image from a positive. In the strictly photographic method, the sheet on which the drawing is to be printed is sensitized by a silver halide emulsion applied by spraying, or by a stripping layer transferred from a temporary support. The drawings can be prepared on sheet material coated with a white layer that fluoresces or phosphoresces in

ultraviolet or under X-rays. The sheet on which the glow is obscured where there are opaque lines drawn is used to print on the sensitized sheet. Alternatively, the fluorescent layer may be overcoated by a photographically opaque layer through which the drawing is scribed, exposing the lines in white fluorescent pigment that can be excited and printed. Copies can also be made by reflex copying to give negatives for contact printing, or by using a camera to give reduced negatives that can be printed by enlargement onto the sensitized sheet.

Photosensitive polymers are used to provide images on metal for subsequent etching to remove unwanted metal, to make printed circuits for electrical equipment, for nameplates, and a variety of purposes.

11. Underwater Photography.—Photographs can be taken of underwater objects such as swimmers and divers, fish, the bottom of the sea, ships' bottoms, and the corrosion of structures. Water absorbs red and blue light strongly, and the dominant colour is blue-green. At depths to 15–20 ft., pictures can be taken with reasonable exposures by using the light penetrating from outside. At greater depths, special lighting equipment has to be lowered into the water. Strong lights are required, particularly for study of the behaviour of fast missiles dropped into water or launched under it. Special cameras in water- and pressure-proof cases have been designed for still and motion-picture photography with flat glass pressure plates in front of the lens. Some attempts have been made to design lenses that can be used with the front surface in contact with the water. There are few special problems involved in photographing underwater through windows, provided the water is clear, the light intensity is adequate, and proper account is taken of reflections and refractions. Surface reflections must be avoided by shielding. Colour photographs will tend to appear blue-green, but compensation at moderate depths may be achieved with daylight-type film with the appropriate colour-correcting filter. During World War II, black-and-white and colour photographs were obtained from aircraft to determine water depths off enemy coasts. A great importance was given to underwater photography through the development of "frogman" equipment during and after World War II, and after the war it became a popular hobby in addition to being of scientific and military importance.

12. Medical Photography.—Among the most important applications of photography in medicine are radiography and photomicrography, which are dealt with as special subdivisions. In the form of the motion picture, medical photography is important for recording and teaching. In still photography its scope has three main aspects; *i.e.*, photography of the living person, photography of surgical operations or methods of treatment, and photography of pathological specimens. Special lighting techniques may be necessary in some cases, but in general the technique is that used in good ordinary photography, but under the supervision of the medical expert. Colour photography is of increasing value. Special techniques in medical photography include infrared and ultraviolet photography, use of special equipment for photographing the eye, and study of body cavities by endoscopic photography in which pictures can be made of the interior of the stomach, larynx, bladder, thorax, and nearly all other body cavities.

13. Document Reproduction.—The reproduction of documents is an important part of applied photography. Its significance lies in its importance for reproducing accurately, for effectively increasing the life of perishable documents, for permitting multiple copies to be stored in different places as a security against disaster, for reducing the storage space of documents, and for retrieving the information in them rapidly, accurately, effectively, and cheaply. Processes are available in which documents may be copied by contact to the same size as the original or copied optically at a reduced scale, giving reproductions that can be read in special viewing devices or that can be enlarged to give photographic prints.

Direct copies on paper of the same size as the original are used for business papers, printed material in general, notes for research, musical scores and parts, drawings, insurance policies, etc. They may appear as positives (dark on a light ground) or as negatives (light copy on a dark ground). Reduced-size copies are usually made on film, generally 16, 35, 70, or 102 mm., or in certain cases on sheet film, and a fair percentage of document reproduction to reduced size is done on cards. Enormous quantities of a great variety of documents are copied on film (microfilming)—for instance, bank, business, and insurance records, official documents, military documents, books and periodicals from libraries, engineering drawings, etc. Reproduction on cards is widely used for books, periodicals, and abstracts of literature. Combinations of microfilming and cards have been used in which the film transparency is inserted in a hole in the card, which also carries reference information and can be filed and punched for use in sorting machines.

Reproductions on paper to the same size as the original, or to approximately the same size as the original, can be done by contact printing through the document onto photographic paper if the original is printed on one side only; thus is produced a negative from which prints can be made, or a negative print in which the type matter is not reversed if the back of the document is placed in contact with the sensitized paper in printing. In the case of double-sided or opaque originals, reflex copy negatives can be made as intermediates for obtaining prints. Image-transfer processes are widely used for this purpose to give positive copies directly. If large production is involved or if the copy is to be changed in size, special cameras for photographing onto paper are used, among the best known being the Photostat, Rectigraph, Haloid Foto-Flo, Dexigraph, and Rutherstat machines.

The earliest large-scale commercial use of greatly reduced-size copying onto narrow rolls of film resulted from the introduction of the Recordak system by the Eastman Kodak Company in 1928. Continuous, automatic cameras photographed documents on 16-mm. film and the first large use was for copying checks in bank transit or clearing work, but it soon spread to a great variety of applications and to use of 35-mm. film as well as 16-mm. film. A special use of the method, known in England as Airgraph and in the United States as V-mail, was developed in 1941 for distributing mail to and from the armed forces overseas. Storage of engineering drawings is greatly facilitated by copying onto narrow roll or small sheet films, and paper reproductions can readily be made. Many libraries have document copying services and when the volume is large automatic and continuously operating systems based on intermediate microfilms are used.

In the drawing office, copies of tracings are made by blueprint, iron-silver, ferric-gelatin, and diazotype processes, and by special types of paper that give ordinary silver images and can be handled in room light. When a great many reproductions of a single original are required, it is often convenient to print from lithographic printing plates, and simplified ways of putting the image on the plate are available.

14. Recording Cameras.—Among the uses of cameras for special recording purposes may be mentioned the following: gun cameras, used for training in aerial gunnery and for recording the effectiveness of gunfire in combat; phototheodolites for survey from the ground and for plotting the position of shell bursts; submarine periscope cameras for photographing through the periscope the results of torpedo fire and enemy coast lines; cameras provided with enclosed lights for photographing fingerprints and instrument panels; special cameras frequently using invisible rays for photographing aircraft instrument panels; cameras for photographing inside tubular cavities such as gun barrels and oil well bore holes; endoscopic cameras for photographing inside body cavities, radarscope and other cathode-ray tube cameras.

15. Photographic Photometry.—The intensity of radiation can be measured by photography. The radiation whose intensity is to be measured is compared with that from a standard source by matching the densities of photographic images produced by both. A number of conditions have to be met, and they are described in the publications on the subject. (*See* also PHOTOMETRY.)

16. Phototopography.—Col. Aimé Laussedat of the French Army pioneered the application of photography to surveying, especially in the Alpine regions, and it was applied extensively in Canada, especially by E. Deville. Practically all photographic

survey is done from the air. In ground phototopography, special cameras (phototheodolites) are used after the manner of theodolites, and photographs are taken in pairs from the ends of measured base lines, in such a way that the subject can be identified in both photographs. The cameras have means for orienting them precisely in relation to the subject, levels for setting them true to the perpendicular, and means for properly orienting the image inside the camera. Plates are usually used unless easy portability is important; and exposures may be long, so the plates may be relatively slow and of high resolving power. Special phototheodolites have been used for determining the position of antiaircraft shell bursts and to follow the course of space vehicles and similar distant objects. (*See* also PHOTOGAMMETRY.)

17. Aerial Photography.—The first aerial photographs of the ground were made from captive balloons (Nadar, 1858; S. A. King and J. W. Black, 1860) using wet collodion plates. The principal early development of aerial photography came after the advent of the airplane, particularly during World War I. In the last year of that war, thousands of photographs were taken each day for intelligence purposes. During World War II, millions of photographs were made from the air and more than 80% of the knowledge of the enemy was derived from them; the same was true during the Korean War.

The chief uses of aerial photography are: (1) in military intelligence, for recording troop movements, positions, defenses, supply facilities, bridges, railways, docks, industrial establishments, shipping, etc., orientation of bombers and bomb damage assessment (in the military field, aerial photography may sometimes be done indirectly by photographing the face of the radar tube and by using "unaccompanied" cameras in missiles and drones); (2) in mapping, military and civilian, to provide the basis for making new maps and filling in detail or revising existing maps; (3) for mosaics, which are composite aerial photographs made by joining a number of separate photographs of the ground; (4) in making survey photographs for purposes of forestry, oil, geology, crops, soil erosion, archaeology, traffic distribution, real estate, exploration, city planning, and such studies.

Aerial photographs are made in cameras specially mounted in airplanes so as to minimize vibration; the photographs are called vertical or oblique according to the orientation of the camera to the ground. Early aerial cameras were modifications of existing plate cameras but they were provided with magazines permitting exposure of a number of plates in rapid succession. With the exception of a few special survey cameras that use plates, aerial cameras now use rolls of film that can be moved intermittently by hand or generally by an electric motor controlled by an intervalometer in order to make series of photographs of the ground along the line of flight. These photographs are usually arranged to overlap about 60% so that they can be viewed stereoscopically when maps are being plotted from them, or when it is desired to study ground detail.

Film for general aerial photography is of the high-speed panchromatic type, with extra red sensitivity to permit short exposures through filters. Special fine-grain films giving high resolution are used where the maximum information is required from the photograph. Infrared film is used for long-distance and high-altitude photography, for camouflage detection, and for forestry survey. Colour film was first used in aerial photography in World War II. The colour contrasts aid identification of objects, show up underwater features, and permit night photography of coloured flares.

Aerial films range in width up to 20 in. and up to 400 ft. in length. The film support for aerial photography is mainly of the topographic variety, which undergoes little dimensional change in processing or with change in humidity and so reduces the errors that must be corrected in plotting maps from the photographs.

A wide variety of lenses is used, ranging in focal length from about 3 to 100 in., and in aperture from *f*/8 to *f*/1.5. (See *Photographic Lenses*, below.)

In aerial photography the camera is moving in relation to the subject photographed, and exposure times must be very short or the picture will be blurred. Use is therefore made of high-speed shutters of the focal-plane, louvre, and between-the-lens types. For night photography using flash bombs, special shutters are operated by a photocell circuit activated by the light of the flash.

Instead of, or in addition to, using high-speed shutters, compensation for movement of the image can be effected by moving the lens during exposure, moving the film continuously through its magazine at the same rate the image moves, the exposure being made continuously through a narrow slit in the focal plane, or by moving the film in its magazine but exposing the full picture area intermittently as in ordinary photography.

In order to photograph large areas of ground at one time, wide-angle and short-focus lenses, or multiple-lens cameras, or groups of separate cameras may be used. Multiple-lens cameras having three, four, five, and nine lenses have been developed. In the Tri-Metrogon system developed for rapid survey during World

War II, three cameras are used, one vertically and two obliquely, one on each side of it, the photographs being made to overlap somewhat to cover the entire ground from horizon to horizon on each side.

Atmospheric haze presents a serious problem for aerial photography since it tends to lower the contrast of or to obscure ground detail. Haze scatters blue light preferentially and transmits the longer wavelengths. Its effects can be largely eliminated by using panchromatic film and filters that absorb blue light. The commonly used filters are yellow, but for better haze penetration it is sometimes necessary to use red filters, or in extreme cases to use infrared-sensitive film and a deep red filter. In this case the apparent increase in haze penetration may be due partly to the selective penetration of the infrared and partly to an increase in the contrast of the ground resulting from the special reflectance characteristics in the infrared of the objects on it. Special filters also are used for other particular purposes, for instance, green filters for distinguishing certain kinds of vegetation.

Film for aerial photography is developed in the roll on special machines in which it moves continuously through a series of tanks, or back and forth from one reel to another in single tanks, or on spiral reels or racks that can be immersed in the solutions for the desired times.

18. Radiography.—In this branch of photography, photographs are produced on film by the passage of X-rays or gamma rays through an object. There are several aspects: medical and dental radiography, which is by far the widest use; industrial radiography for examination of the interior condition of solid objects, especially castings, welds, and structures, usually of metal; gamma radiography, for examination of the interior state of solid objects, but using gamma rays from radium or radioactive isotopes; X-ray diffraction for the analysis of the atomic and molecular structure of materials. In autoradiography the specimen emits radiation and is placed in direct contact with the film.

Radiographs, other than diffraction photographs and autoradiographs, are shadow photographs obtained by passing a beam of the rays directly through the object, which absorbs them to an extent depending on its atomic nature and thickness. Photographic films are sensitive to X-rays and gamma rays, as they are to light, and when the exposed film is developed, the image varies in density according to the extent to which the rays were absorbed. The invisible internal structure is thus revealed.

The earliest radiographs were made in 1896, the year in which Wilhelm Röntgen discovered X-rays, and the glass plates then available were used. Modern radiography is done on film coated with a special emulsion, and usually on both sides to give maximum speed and contrast. Only a very small percentage of the X-ray beam is absorbed by the emulsion, and in order to increase the effectiveness of the exposure the film is usually put between two "intensifying screens," which are coated with a layer of material such as calcium tungstate that fluoresces under the action of the X-rays; the fluorescent light augments the exposure caused by the X-rays. For some classes of industrial radiography, thin lead foil screens are used to improve the contrast and clarity of the photograph. For dental radiography and some industrial work, no intensifying screens are used.

The penetrating power of X-rays depends on the voltage between the filament and target in the X-ray tube; the higher this voltage, the "harder" or more penetrating are the rays. For general medical radiography 40–80 kv. may be used, the higher values being for the thicker body parts. For industrial radiography, voltages ranging up to several million may be employed. X-rays generated at high voltage for radiography of metals are so penetrating that materials such as cloth, paper, and leather appear quite transparent to them, and low voltages of 4–20 kv. must be used with them.

When X-rays strike an object, a considerable percentage of them is scattered, in much the same way light is scattered by fog. The scattered rays tend to cause a veil over the radiograph and so reduce contrast and detail. This effect can be offset by using a Potter-Bucky diaphragm, which consists of a grid of alternate strips of lead and wood that is moved between the object and the film during the exposure. The direct X-rays pass through the wooden strips, while the lead strips absorb those scattered sideways. The grid is moved to prevent its casting a shadow but sometimes a stationary Lysholm grid of thin, closely spaced lead strips is used.

Medical uses of radiography include location of foreign bodies and cavities; studies of fractures; diagnosis of tuberculosis and abnormal conditions of the digestive and urinary tracts, the heart, the spinal column, and the sinuses; and in the case of dental radiography, studies of cavities, abscesses, unerupted teeth, pyorrhea, and many other conditions.

The widest use of industrial radiography is in the examination of interior structures for hidden faults, without involving damage to the object, for instance, in castings and welds, assembled mechanisms, molded plastics, munitions, and a vast range of manufactured products.

Among special radiography techniques may be mentioned: body-section radiography in which only one plane of the body gives a distinct image, nearer and farther parts being blurred, the result being obtained by moving the film and X-ray tube in opposite directions about a pivot point in the plane that is to appear sharp; roentgenkymography, used for study of moving parts, such as the heart, by moving between the patient and the film during exposure a lead plate with a series of horizontal slits; microradiography, usually for thin specimens of low X-ray absorption, with very fine detail, in which the radiograph is made on fine-grain film and subsequently enlarged; high-speed radiographs have been made in $\frac{1}{1,000,000}$ sec. for ballistic and other high-speed studies.

There developed, particularly during World War II, a need for radiography on a large scale, particularly for making X-ray photographs of the chests of people being examined for induction in the armed forces. Mass miniature radiography was introduced. In Europe, photographs of the fluorescent screen image were made on 35-mm. film, using lenses of very high aperture. In the United States, the preferred size was 4×5 in., stereo pairs being made on film 4×10 in. in size. In motion-picture radiography, or cineradiography, motion pictures are made of the image on the fluorescent screen, or, less frequently, series of natural-size radiographs are made in quick succession. Usually one cycle of movement of a part is photographed, and in projection it is viewed in repeated succession. The chief limitation in this work was that lenses of extremely high aperture were required in order to keep the X-ray dosage to the patient at the minimum. However, image amplifiers came into use, so that low exposures to X-rays could be given the patient and low exposure to the film. In gamma radiography, the gamma rays from radium or radioactive isotopes are used. They are of shorter wavelength than X-rays and thus have greater penetrating power. They are specially used in the radiography of thick metal specimens.

Radiographs are usually examined as the negatives, and in order to give the impression of depth they are frequently made in pairs, using two positions of the X-ray tube, and viewed in the stereoscope. In X-ray diffraction methods, the internal structure of crystals may be determined by the diffraction pattern photographed on passing a beam of X-rays through a single crystal or a sample of the material in powder form. Autoradiography is a procedure that originated when radioactive isotopes became available. It is known that when isotopes are introduced into an organism, they localize in certain tissues and, in some cases, in specific portions of the living cell. These concentrations of the radioactive substances can be detected by placing thin sections of the tissues in close contact with special photographic plates. Upon development of the plate, black specks identify the location of the concentrations of the radioactive materials. By using fine-grain materials and magnifying the resultant image microstudies are possible. (*See* RADIOLOGY; X-RAYS.)

19. Nuclear Particle Recording.—Direct recording of charged atomic particles by photographic emulsions provides an important adjunct to the ionization chamber, the Geiger counter, and the Wilson cloud chamber in atomic physics. The effects were first found with alpha particles, which produce a track of silver grains in the developed emulsion. It was later discovered that the paths of protons could also be recorded and that the tracks had a different grain spacing than alpha particles. Cosmic ray particles give nuclear disintegrations on collision with the atoms in the emulsion, and star patterns arise, consisting of the tracks made by the particles from the atomic nuclei. Tracks of electrons, and effectively any charged particle of any energy, can be recorded on special thick emulsions with a high silver bromide content, small grains, low fog, and of a speed designed for use with the particle concerned. The tracks are caused by grains being made developable by ionizations within them resulting from impact of the particle. The tracks are examined and measured by special microscopic techniques.

IV. COLOUR PHOTOGRAPHY

In 1810 J. T. Seebeck, in 1840 Sir J. F. W. Herschel, and later Edmond Becquerel and Abel Niepce de Saint-Victor observed that silver chloride darkened by exposure can record the spectrum of the sun by its direct action, in colours similar to those of the spectrum itself. The colours cannot be fixed and the method has no practical value.

The first fixed colour photographs from nature were made by G. Lippmann in 1891, using the interference principle, the possibility of which had been pointed out by W. Zenker (1868), Lord Rayleigh (1887), and O. Wiener (1890). Beautiful colour reproductions can be obtained, but the plates are insensitive, the viewing is not convenient, and only one photograph can be obtained.

The basic principles of modern colour photography are derived from an experiment made in 1861 by James Clerk Maxwell in a study of the theory of colour vision. He photographed coloured ribbons through red, green, and blue filters, from the negatives made three positive black-and-white transparencies, and projected these in register onto a screen using three lanterns, each transparency being projected by light of the colour by which its negative was taken. The image on the screen was a colour reproduction of the ribbons.

In 1869 Louis Ducos du Hauron published a book in which he laid down the principles that provide the basis for modern processes of three-colour photography. At about the same time Charles Cros published an article with much the same conclusions. Ducos du Hauron's book gives a clear account of the two fundamental processes of colour photography, the additive and the subtractive, with suggestions for carrying them out. The practical development of the processes was delayed until panchromatic plates became available through the introduction of colour sensitizing by Vogel in 1873 and the introduction of isocyanine and carbocyanine sensitizers early in the 20th century.

The additive process, which was almost entirely replaced by the subtractive processes after 1935, is used only for transparencies for projection and direct viewing; the subtractive processes can be used for transparencies and for paper prints to be viewed by reflected light. In both cases the first step is to make three separation negatives of the subject by the red, green, and blue light from it. It is also possible to make colour photographs by the two-colour process, in which the separation negatives are made by half the spectrum, blue-green and orange, but the best colour rendering is obtained by the three-colour process.

1. Additive Processes.—In the additive processes, the colours are produced by adding together varying amounts of red, green, and blue light. There are three main processes of additive colour photography: triple projection, screen unit, and lenticular film.

In the triple projection process, black-and-white positives made from negatives exposed through red, green, and blue filters are projected through similar filters in register on a screen, as in the original Maxwell experiment. Special equipment for making the three negatives in succession or simultaneously were put on the market, together with lanterns for projection. Ducos du Hauron,

Cros, and F. E. Ives invented devices for viewing the three pictures directly rather than by projection. In the photography of stationary objects, the three negatives can be exposed in succession. In the case of moving objects, however, the three negatives must be made simultaneously, otherwise colour fringing will occur. For simultaneous exposure of the three negatives, use is made of groups of lenses or of beam splitters consisting of a group of mirrors or prisms. Another system for making these three negatives, originally invented by Ducos du Hauron, is the so-called tripack in which three separate films are arranged behind each other, with filters to ensure that the red, blue, and green records are obtained separately, one on each film.

In the triple projection process good colour quality can be obtained, but the system is complicated and has never been a commercial success.

2. The Screen Unit Process.—The first commercially successful colour process, the Lumière Autochrome plate, brought out in 1907, utilized the screen unit process. This was a modification of one form of additive process suggested by Ducos du Hauron. Instead of making three separate negatives through filters, a single plate was covered with minute blue, green, and red filter elements. A panchromatic emulsion was coated over this layer. The exposure was made through the filter layer so that the image obtained was broken up into tiny units representing blue, red, and green components of the colours of the subject. The emulsion was developed by the reversal process to give a direct positive in black and white, which, on direct viewing or projection, gave a reproduction of the subject in colour. Alternatively, if the filter elements were uniformly arranged, the plate or film could be developed to a negative and printed to give a positive transparency that could be registered in contact with a plate carrying minute filter elements to give a positive colour transparency.

The first successful use of the screen unit process was made by J. Joly and by J. W. MacDonough in 1892, the filter elements being on a plate separate from the negative. This arrangement was later employed in the Finlay plate. In the Lumière Autochrome process, the filter layer consisted of dyed starch grains with the spaces between filled with carbon black. The plates gave good colour quality and were on the market as plates and later as films for 30 years. Other screen unit processes were later introduced: in particular, the Finlay process mentioned above, in which the screen was printed in bichromated colloids; the Agfacolor plates and film, in which the filter layer consisted of dyed resin particles rolled flat; and the Dufaycolor process, in which the emulsion was coated on a regular dyed screen pattern prepared on the film support. The Agfacolor and Dufaycolor materials were developed by reversal and were sold as roll, sheet, and motion-picture film.

The screen unit process gave transparencies of good colour quality, but the plates and films were difficult and costly to manufacture. They were dense, so that it was difficult to get enough light in projection, and the screen pattern was frequently very evident.

3. The Lenticular Film Process.—This was invented by R. Berthon in 1908 and developed by A. Keller-Dorian and particularly by J. G. Capstaff and the Eastman Kodak Company; it was made available commercially in 1928 as the Kodacolor process for amateur motion-picture photography in colour. In this process, the film support is embossed with minute cylindrical lenses on the side opposite the emulsion. A three-colour banded filter is used over the lens; during exposure, the embossed side of the film faces the lens. Somewhat as in the screen unit process, the lens forms a full image of the subject on the film, but it is broken up into minute elements that are images of the banded filter formed by the embossed lenses on the film. The film is developed by the reversal method and projected through a three-colour banded filter.

The quality of the results given by the lenticular film was excellent, but disadvantages were encountered in projection, which involved a great loss of light because of the filters, making special projection optical systems necessary, and the lenticular pattern was often very much in evidence.

4. Subtractive Processes.—The subtractive processes are the important practical processes of colour photography. Their principle was first described by Ducos du Hauron, and they are now used practically exclusively for colour prints on paper and transparencies for still and motion-picture projection. In the subtractive process, three separation negatives are first made by red, green, and blue light. From these, positives are made in colours complementary to those by which the negatives were made, and the three are superimposed in register on white paper to give a colour print or on film to give a transparency.

The negative made by red light is printed to give a cyan (blue-green) picture; that made by blue light is used to give a yellow picture, while that exposed by green light is printed in magenta. When these partial images are superimposed, a good colour reproduction can result.

The three separation negatives can be made: (1) separately by successive exposures through the three filters on three plates or films; (2) simultaneously on three plates or films using a one-exposure (one-shot) camera provided with a beam splitter of partially reflecting prisms or thin pellicles or split lenses; (3) simultaneously on a tripack of three films or plates superimposed and so sensitized and provided with filter layers that each records only one of the primary colours; (4) simultaneously on an integral tripack or monopack.

In the first three cases the three negatives are generally used to print three positives, which can be superimposed on paper or film. Various processes have been used, in particular carbon, Ozobrome or Carbro, bromoil, and dye-mordant methods, and differential tanning of a gelatin layer. There are two principal forms of the last-named—the Pinatype process, in which dye is taken up in an amount dependent on the softness of the gelatin, and is allowed to stay in the layer if a transparency is required, or is transferred to gelatin-coated paper by imbibition if paper prints are required; and the Kodak dye transfer process, in which the soft parts of the differentially hardened gelatin layer are washed out, leaving a relief image in hard gelatin that can be dyed and the dyes transferred to paper or film.

5. Monopack or Integral Tripacks.—It is evident that a simpler system would result if the three layers were coated over each other on a single film support. This proposal was first suggested with the idea that the layers should be separated for development and printing, but the manipulation proved to be too difficult for practical handling.

It was next suggested, by K. Schinzel in 1905, that the three superimposed layers should be arranged so that each responds to a single primary colour, that the layers should be inseparable, and that a coloured image should be developed in each. In Schinzel's proposal, dyes of colour complementary to the spectral region of sensitivity were incorporated in the layers, which were to be developed and then treated in such a way that the dyes were bleached, to an extent proportional to the amount of silver developed. C. Christensen in 1918 proposed a similar arrangement, in which the dyes in the layers were destroyed by reduction by hydrosulfite in the presence of the silver image. The silver-dye bleach method was applied by B. Gaspar, in whose process the dyes were catalytically bleached in the presence of the silver, and by CIBA in 1964, as the Cilchrome process for making colour prints from positive colour transparencies.

Most of the modern processes of colour photography depend on the formation of dyes to an extent depending on the exposure and thus the amount of silver developed in the layers inseparably coated one over the other. The colour of the dye in each of the three layers is complementary to the spectral region to which the layer is selectively sensitive. The basic method for producing the colours depends on a discovery made by B. Homolka and worked out by R. Fischer in 1911; they found that when certain developers react with silver halide to form silver, in the presence of a compound known as a coupler, there is formed along with the silver image a dye image in proportion to the amount of silver formed. The developers used are of the type known as diamines, in particular derivatives of *p*-phenylenediamine; by proper selection of the coupler and developer a great variety of colours can be developed, the final dyes usually being of the indoaniline or azomethine types. The couplers that form cyan dyes are usually phenols; nitriles or

pyrazolones are used for magenta dyes; esters, ketones, or amides may be used to form yellow dyes. After the films are developed, the silver is bleached out, leaving the dye images.

Various arrangements of the three basic coatings on the film have been proposed, as well as various ways of introducing the colours. In 1912 Fischer proposed a process using a film with three layers of emulsion coated over each other, each layer containing couplers so that appropriate colours could be developed in them. Fischer was not able to make the process work because he could not prevent the couplers and sensitizing dyes from wandering from the layers to which they applied. It was not until 1935 that the first commercially successful colour process using coupler development was marketed. It was worked out by L. D. Mannes and L. Godowsky and the Eastman Kodak Company, and was called the Kodachrome process.

In the Kodachrome system, three emulsions responding selectively to blue, green, and red light were coated over each other, the blue-sensitive layer being on top and beneath it a yellow-dyed layer to prevent blue light from reaching the two lower layers.

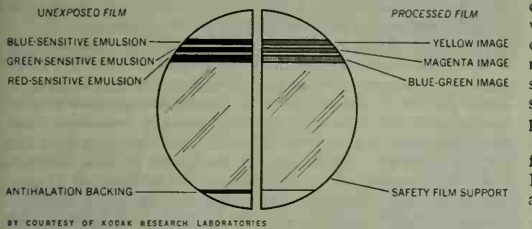

FIG. 4.—CROSS SECTION OF KODACHROME FILM

(By about 1931, nonwandering sensitizing dyes had been developed.) The process was designed to give a direct positive colour transparency. The significant features of the process were that the dye-forming couplers were used in the developer solutions and not in the emulsions, and that the dye images in each of the layers were developed successively in separate solutions using the stages of development, controlled diffusion bleaching, and colour redevelopment, the final step being the removal of the silver to leave the images in the dye alone. Kodachrome film was first made available as 16-mm. film for motion pictures and later was produced as 35-mm. film for slide transparencies, 8-mm. motion-picture film, sheet film, and as reflection prints by coating on a white support (Minicolor, Kotavachrome, and later Kodachrome prints).

The processing of Kodachrome by controlled diffusion was clumsy and toward the end of 1938 was replaced by a selective method in which the assigning of the dyes to their proper layers was determined by the sensitivity of the layers. In this, the film is first developed to give a negative in all three emulsion layers. It is then exposed through the base to red light, which affects the undeveloped parts of the bottom red-sensitive layer, and is then developed in a developer containing a cyan coupler, so that a positive cyan dye image is formed in the bottom layer. By exposing through the front to blue light, an image in yellow dye can be developed in the top layer, and the middle layer can then be made developable and give a magenta image. If the silver in all three layers is bleached out, the dyes alone remain to give the colour picture. The success of the Kodachrome processing depends largely upon using sensitizing dyes that will not wander from their appropriate layers and will withstand processing solutions.

Some time after the introduction of Kodachrome film, Agfacolor-Neu film became available in Germany and later Ansco Color film was introduced in the United States. (After World War II, similar products were put out by Gevaert and Ferrania, among others.) These films differed from Kodachrome film in that the colour-forming couplers were incorporated in the three emulsion coatings rather than in the developer solution, thus permitting simultaneous formation of the three dye images in a single colour-developing step. The couplers were attached to heavy molecular chains that prevented them from diffusing through the gelatin, so that each dye was formed exclusively in its proper layer. These films were also intended to give direct-positive colour transparencies, and processing consisted essentially of (1) developing a black-and-white negative in all three layers, (2) exposing thoroughly to white light, and (3) developing the residual silver halide in all three layers simultaneously in a colour developer, the couplers in each layer forming the proper dyes. Finally, the negative and positive silver images were bleached out, leaving the dyes. Similar materials were later made available on a white base to provide prints for viewing by reflection.
